Inactivated sera, after absorption with untreated sheep cells, are set up in serial doubling dilutions of 0.25 ml unit volume in 3 x 1/2 in tubes. To each is added 1 vol of sensitised cell suspension and 2 vol of complement containing 1 Kolmer unit. Appropriate controls (serum + untreated cells, sensitised cells + complement, sensitised cells + saline, known positive and negative sera in full) are set up and the whole incubated for 1 hr at 37°C. The end point is taken as the highest dilution showing sparkling haemolysis (titres given are reciprocals of the original and not the true final serum dilution).

Sensitised cells are prepared by treating packed washed sheep cells with 10 vol of 0.1% polysaccharide in saline solution for 2 hr at 37°C, washing three times with saline, and resuspending to 0.5% concentration in saline solution. With the defined reacting system no differences were noted between 0.5, 1, and 2% suspensions, the first was selected as conserving polysaccharide. Sensitised cells seem to be more stable than untreated cells, suspensions remaining potent and unhemolysed for a week or more at 20°C. The 0.1% polysaccharide concentration is arbitrary, but that of *N. gonorrhoeae* requires to be of this order, *S. typhi* O polysaccharide is active in dilutions of 1 x 10⁻⁵. Cells sensitised with gonococcal polysaccharide show a relatively rapid loss of sensitivity and, when tested against the same serum, may show a fourfold to eightfold reduction of titre in 3 or 4 days. Per contra this may be due to instability of the natural antibody and the point, being of practical importance, required further investigation.

We have prepared serologically active polysaccharide fractions by the following methods:

i Rapid freezing (dry ice-alcohol) and thawing (56°C) twenty times

ii Papan digestion for 6 hr at 52°C at pH 6 of fresh suspensions from solid media or of acetone-dried bacterial bodies (Freeman et al. 1940) followed by neutralisation with 1/10 NaOH

iii Treatment of similar suspensions with the lytic product of *Streptomyces albus* (Vaxted 1948)

These methods yield a polysaccharide containing supernatant fluid which may be used directly for sensitisation.

iv Precipitation of the F68 polysaccharide by 68% v/v ethanol from ice cold trichloroacetic acid extracts of acetone dried bacterial bodies (Boivin et al. 1933), the product is purified by dialysis and dried in vacuo from acetone.

v Ethanol precipitation from an alkaline hydrolysate (N/4 NaOH) of large volume (10 litres) 10-day broth cultures (Ashenburg et al. 1950). The crude precipitate is purified from solution in 0.1M sodium acetate/acetic acid buffer (pH 4.8) by repeated extractions with a chloroform/n-butanol mixture, reprecipitated with 1.5 vol of ethanol and dried in vacuo from acetone.

Both these methods yield a pure dry polysaccharide which can be used quantitatively. Method v gave maximal yields and seems to be that of choice for large scale production.

vi Alkaline hydrolysis (N/4 NaOH) for 6 hr at 56°C of a heavy suspension or dense fluid culture and precipitation with 68% v/v ethanol. The polysaccharide is allowed to precipitate overnight at 2°C collected by centrifugation, and either acetone dried for storage or used directly.

A single experiment of note was the preparation of the pure FX flagellar antigen d of *S. typhi* from the cells of a

formolised broth culture (250 ml) by extraction with 10% diethylene dioxide and precipitation as a filmy cloud by half saturation with $(\text{NH}_4)_2\text{SO}_4$ (Jenkins 1946). The precipitate taken up in saline solution gave a precipitin reaction to titre with *S. typhi* H serum and a P.L.T. to titre with the same serum when adsorbed on to sheep cells. The interest lies in the fact that the antigen is a pure protein.

TUBERCULOSIS

The observations of Middlebrook and Dubos (1948) have been confirmed by the P.L.T. in tuberculosis with a tuberculo polysaccharide prepared from Old Tuberculin (supplied by Messrs Burroughs Wellcome & Co.) by dialysis against running water for 18 hr followed by frequent changes of distilled water for 18 hr. The dialysate was concentrated to a quarter of its original volume in vacuo and adjusted to pH 7.2 before use as a direct sensitising agent. Further work on the extraction of active fractions from both the bacterial bodies and the substrate of fluid cultures of the H37rv strain is in progress.

A preliminary series of 50 sera from persons with no history of either tuberculous or gonococcal infection gave uniformly negative results. A similar series was then provided by Dr A. M. Beemer, of King George V and Springfield Hospitals for Tuberculosis, Durban, from patients with both positive and negative sputum tests. In every case of active disease the P.L.T. was positive, the titres ranging from 6 to 64. The results in negative sputum cases were variable, and the clinical assessment of the test and the relations between the P.L.T. titre and the stage of activity of the disease have yet to be determined; this will depend on the large scale production of the polysaccharide. Moreover the multiple polysaccharide complexes of the tubercle bacillus require further investigation; the isolation of serologically active but distinct fractions from the human and bovine strains which could be adapted to this technique would represent a distinct diagnostic advance.

The specific neutralising action of the tuberculo polysaccharide was demonstrated by fixing equal volumes of dialysed tuberculin and positive serum for 1 hr at 37°C. Hemolysis did not take place on the subsequent addition of sensitised cells and complement.

GONORRHOEA

Serologically active fractions were obtained from *N. gonorrhoea* by methods I, II, and VI, first from a pooled batch of time expired gonococcal vaccine, and subsequently from the parent vaccine strains Rietfontein 1 and 4, supplied by Dr D. Ordman, of the South African Institute for Medical Research, and from a local strain, w190. The vaccine yield was adequate but low; partial extraction and degradation of the polysaccharide had taken place during 28 months' storage in 0.5% phenol, as shown by the fact that an inactive polysaccharide fraction could be precipitated from the supernatant fluid. Since at least two serological strains exist, determined by specific polysaccharides (Casper 1937), it is desirable, for practical purposes, to use mixed strains for preparing active extracts. Any solid medium supporting prolific growth is suitable; we have used dextrose starch agar and are now investigating a supplemented papain digest broth (modified from Le Minor 1948) for large scale production by method v.

Our purpose was to investigate the possibility of substituting the P.L.T. for the gonococcal complement fixation test, which presents a number of difficulties apart from that of interpretation, chief among which are the low titres to which antibodies are demonstrable in serum, the relative instability of the antigen, and the frequency of anticomplementary reactions. A preliminary series of controls (some sera as for tubercle P.L.T.) gave uniformly negative results. Sera from both acute and

chronic cases were then tested in parallel with the complement fixation test. With one exception the results of both tests were negative in acute cases; the one case was in an African with an acute infection (which may have been superimposed on an older one) whose complement fixation test was negative and P.L.T. positive to a titre of 8. Of ten chronic cases the complement fixation test was anticomplementary in 1, the remaining serum titres being 1/4-4, 1/2-4, and 1/4-1. The P.L.T. was positive in all the cases, the titres being 1/4-5 (of which three were not taken to end titre), 1/8-3, and 1/64-1. The P.L.T. was negative in a series of cases of non specific urethritis.

The specificity of the two tests seems to be of the same order, with the balance slightly in favour of the P.L.T., the sensitivity of the latter is demonstrably greater, P.L.T. titres being from 4 to 16 times as high as those shown by the complement fixation test. Moreover, the P.L.T., using a specific polysaccharide quantitatively in a pure form, overcomes the vagaries of a bacterial antigen and its standardisation, eliminates its frequent anticomplementary action, and, so far as we can determine, allows the test to be made on mildly hemolysed sera which vitiate the complement fixation test. For these reasons we believe that the P.L.T. should supersede the complement fixation test as a diagnostic test.

COMMENTS

The principle of the P.L.T. is probably applicable to any condition in which serum antibodies are formed in response to an infecting agent from which a specific active fraction can be extracted—e.g., tularaemia polysaccharide hemagglutination test (Alexander et al. 1950). Apart from bacterial infections, the rickettsial, spirochetal, and protozoan infections would probably repay immediate study.

The underlying mechanism of the test also requires study. Although many bacterial polysaccharides have been shown to be capable of adsorption on to erythrocytes as well as pure protein fractions, not all serologically active polysaccharide complexes are so adsorbable—e.g., the polysaccharide blood group A complex cannot be adsorbed on to human group O erythrocytes. Nor can all active fractions be adsorbed on to all types of cell; those of *Pfeifferella mallei* can be adsorbed on to human, horse, sheep, guinea-pig, and chicken cells but not on to ox or pig cells, and differences in the amount of active principle required to sensitise different species exist (Boyden 1950).

Since this paper was written, Adler (1950) has reported a specific hemolysis of this type with *S. typhi* O-901 polysaccharide and rabbit immune serum, using sheep, rabbit, and human erythrocytes.

Reviews of Books

The Breast

Structure Function Disease Editor F D SANER, F.R.C.S. surgeon, Royal Northern Hospital, Bristol
John Wright & Sons 1950 Pp 316 45s

THIS book is a symposium by fifteen contributors under the editorship of a surgeon. Its value lies in its many-sidedness and in the fresh authoritative manner in which it is largely written, more particularly where it describes the pathology and biology of cancer of the breast and methods of dealing with it. It offers descriptions of new or relatively new techniques such as biopsy, the exploration of the lymph gland of the second intercostal space, and the limitations of the use of radioactive phosphorus in the diagnosis of malignancy. It also includes an account of plastic surgery for secondary repairs and for æsthetic reasons. One chapter gives a lucid though perhaps slightly personal exposition of the principles governing the use of radiotherapy, and an appendix of statistical data brings into perspective the importance of breast cancer.

In the 316 pages there are nearly 200 illustrations and diagrams. The textual space for each subject is therefore limited, and though fairly common hormonal curiosities such as gynæcomastia receive their due, normal function is scarcely touched upon. But for its size the book is a useful guide for the practitioner in the diagnosis and treatment of pains and lumps in the breast.

The Nutritional Improvement of Life

HENRY C SHERMAN, Mitchell professor emeritus of chemistry Columbia University, New York; Columbia University Press, London; Oxford University Press, 1950 Pp 270 24s

Professor Sherman is a dove of American nutritionists, for his early work with Atwater was published as long ago as 1901. This book he says, completes a trilogy with his well-known works *The Science of Nutrition* and *Food: Their Value and Management*. It is essentially a history of the discoveries in nutrition during the past fifty years, and an attempt to assess the human implications of the new knowledge. Medical readers will be charmed by the clear manner in which both old and new problems are set out, and will be grateful for the excellent bibliography; yet they will be infuriated too for often just when the argument is becoming intricate and interesting, there is an abrupt change down to a simple presentation of well-known facts. Professor Sherman has never really decided for whom he is writing. "Here," the publishers declare, "is the book for everyone, layman or student, who has any interest in the science of nutrition"; but there is far too much tough and disputatious matter to justify this claim. The book deals well with the evidence that by proper attention to nutritional principles we can "both add life to our years and add years to our lives." We trust that Professor Sherman will continue to demonstrate this in his own person and that in due course his trilogy will grow into a pentateuch. Could book IV be for the pundits and book V for the debutantes, please?

The Physiology of Tissues and Organs

Douglas H K. LEE, M.D., F.R.C.P. professor of physiological climatology Johns Hopkins University, Baltimore, Springfield Ill; C C Thomas, Oxford; Blackwell Scientific Publications, 1950 Pp 159 30s

IT is always a problem to know where to begin when teaching physiology to students who have only an elementary knowledge of the science of non-living things and of dead specimens of things that once lived. Should one begin at once with a systematic study of physiology and hope that by the end of the course the principles will be plain, or should one skim through the whole subject, building a framework on which, later, the detailed structure may be supported? If the former method is used some students give up hope and conclude that the subject is too obscure for their understanding. If the second method is tried some grow bored at apparent repetition. In either case only the more intelligent or

keen realise until much later the links and difference between animate and inanimate, and between all living things. Professor Lee has chosen a third way. He has tried to progress from the familiar background of physics and chemistry to the unfamiliar complexities of the living cell, both in general and in the basic vertebrate types in particular and from thence to cell arranged to form organs. The organs are considered from the functional point of view. First the requirements for the efficient performance of a given function are outlined and next the way in which organisms' cells meet these requirements.

The book is based on class and lecture notes, and the subject matter is condensed. It does not pretend to be other than elementary and stops before the stage of considering systematic physiology is reached. It is refreshing in its approach to the subject and succeeds in suggesting in small compass many interesting possibilities and general principles that should whet the appetite of the beginner. It can be recommended as an introduction to physiology.

Technique of Analytical Psychotherapy

WILHELM STEKEL, Translated by Eden and Cedar Paul, London: John Lane, 1950 Pp 403 21s

THIS is a revised edition of the book published in 1931 in which Stekel described his technique for short analysis lasting three to four months. It remains an interesting and stimulating work, with a great deal of practical advice on such matters as the selection of patients, the beginning of treatment, the management of the transference, and the therapist's relations with the patient's family, and the plentiful case-histories are full of instances of Stekel's intuitive skill. His theories do not always convince, and his psychopathology is an eclectic assortment of theories gathered from Freud, Jung, Adler, Nietzsche, and Schopenhauer which he makes little attempt to weld into a formal whole. He lays much stress on the individual, regarding each patient as a unique case for the therapist's study and mastery, and it is as a brilliant tactician rather than as strategist that he will long be remembered.

Industrial Health

An Introduction for Students R PASSMORE, M.A. D.M., lecturer in physiology department of public health and social medicine, University of Edinburgh; CATHERINE N SWANSTON, M.B.C.S., D.P.H. D.I.H. lecturer in industrial health in the department of Edinburgh; E & S Livingstone, 1950 Pp 110 4s 6d

WITHIN the limits set by the authors in their preface, this is a successful book. Their aim is to set forth the rules of industrial hygiene, which are, they say, based on 'simple and straightforward principles of human physiology and psychology'. But in the text they contrive to show that the whole subject is not really very simple. The book emphasises the physiological and sociological rather than the strictly medical and pathological aspects of the subject, and therefore it is somewhat unbalanced. There is a tendency nowadays to soft-pedal the clinical and pathological aspects of medicine and to beat the big drums of sociology. Another way of putting it is that groups rather than individuals hold the stage. It is often forgotten that the individual is just as important as the group. For these reasons we hope that in their next edition Dr Passmore and Dr Swanston will add more about medicine and that they will write more for doctors (and budding doctors) and less for laymen.

In 110 pages they manage to give a surprising amount of information about the distribution of man power in Great Britain, differential mortality rates, production figures and labour turnover. The physical and psychological factors of environment which adversely affect the workers' health are ably discussed. On factory legislation it is stated that laws can only lay down minimal standards which are easy to attain and which everyone recognises as just. It would be interesting to have the opinions of employers as to whether they regard the requirements of the Factories Acts and its numerous regulations as minimal and easy to comply with, contrary to what this book suggests: there are few employers who reach in all respects the standards set by the factory

laws. But apart from a few such highly debatable statements, the information given is accurate, and the book is a stimulating introduction to industrial medicine in its sociological aspects.

Social Medicine

Editor IAGO GARDSTON, M.D. New York Commonwealth Fund 1949 Pp 294 \$2.75

THE high cost of medical care and the narrowness of current medical education led to the convening of a conference on social medicine as part of the centennial celebration of the New York Academy of Medicine. Such a representative gathering including, inter alia, historians, physicians, public-health and nutrition experts, psychologists, and sociologists, expressed in corporate form the underlying conviction that "the days of monastery medicine and the ivory tower are gone." This book is a symposium of the papers contributed during the conference.

The early chapters are devoted to an excellent historical review of the changing relations between medicine and society since the days of Ancient Greece. The portrait of the evolution of social medicine is very clear. Though the individual contributions to the section dealing with the scope and objectives of social medicine are first rate, the picture as a whole is ill defined: too many varying definitions tend to confuse the reader. The chapters on epidemiology and nutrition are good, but the comprehensive account of the social applications of psychiatry is too weighty for easy assimilation.

The editor has succeeded reasonably well in the difficult task of welding so many individual contributions into a coherent whole. He has been helped to achieve this by the final contributor to the symposium who makes an eloquent plea for medicine to widen its sphere of interest by close association with the social sciences. Much physical and mental ill health could be prevented if the medical profession had a better understanding of the social relationship of man. In this respect undergraduate education is all important, for the good family doctor is a sine qua non in improving the health of the individual citizens who constitute the real wealth of the nation.

Die Gewebsmastzellen im menschlichen Knochenmark

P. BREMY, Dr med. Zurich. Stuttgart: Thiemo 1950. Pp 78. D.M. 7.20

THE mast cell has had relatively little attention from English writers. This volume reviews the literature on its origin, morphology and distribution, and quotes work suggesting that its function is bound up with the production of heparin and possibly histamine. Mast-cell tumours have been encountered only in animals. In human subjects increase of the mast cells in the marrow is seen in severe infections, toxic conditions, amyloidosis, and after X-ray irradiation. Dr Breyer presents 20 cases of his own, showing increased mast cells in the marrow, 5 were cases of anaemia due to tumours, 7 had aplastic anaemia, 1 had hemochromatosis, 3 had Marchiafava hemoglobinuria and in 4 the origin of the anaemia was unknown. It is suggested that the increase of mast cells is a defence mechanism. The book is illustrated by a few unimpressive photomicrographs in monochrome.

Personality in Peptic Ulcer

A. J. SULLIVAN, M.D. head of the section of gastroenterology, Ochsner Clinic, T. E. McKEL, M.D., member of the staff of the clinic. Springfield, Ill.: C. C. Thomas Oxford. Blackwell Scientific Publications 1950. Pp 112. 21s. 6d.

ALL interested in peptic ulcer will enjoy reading this little book, written by physicians for physicians, and based on the observations of two gastroenterologists of the Ochsner Clinic, Tulane, who studied the psychic as well as the somatic aspects of something over 1000 peptic ulcer patients. Their technique of establishing personality traits is simple and could readily be repeated. They recognise a main personality type which accounted for 72% of their patients, indeed the characteristics of this type, they say, can usually be demonstrated in less than five minutes of questioning. They call the integrating drive in this behaviour pattern a "craving

for superiority," and are impressed by its "healthy" concern with solid achievement, for in its search for new goals it rides roughshod over all forms of self-indulgence, such as holiday making, sleeping, and even eating. It is one thing to recognise a need for superiority but to raise it to the status of "a primordial urge for success" betrays an excess of zeal over prudence in the investigators. Their peptic ulcer type is the extravert philistine who works at high pressure, talks big, admires skyscrapers, and thinks in terms of material achievement. American culture, rather than a "primordial urge," is at the back of this emphasis on, and concept of, success. This type of personality was absent in 11% of their patients; these had an underlying need to be fed and be taken care of, consistent with the psychoanalytic concept of peptic ulceration formulated by Franz Alexander. The book has a number of entertaining visual aids intended to fix the personality traits in a student's mind. The authors give illustrative case histories, and present a formula embracing the important variables of heredity, emotional situation, local trauma, and intrinsic gastroduodenal factors. They suggest that the relative value of each should be explored and treatment undertaken accordingly.

Some Applications of Nuclear Physics in Medicine

W. V. MAYNEORD, D.Sc., F.R.S.T.P. London. British Institute of Radiology. Suppl. no. 2. 1950. Pp. 290. 35s.

THE chief applications here considered are those of beta-radioactive phosphorus, iodine, iron, and sodium, though cobalt comes in as a gamma ray source of growing importance. The radiologist will be fairly certain of getting the sort of information he needs, whether it be as a therapist or diagnostician; this applies not only to the actual nature of the substance in question and to the kind of radiation it emits, but also to the methods of dosimetry suitable to the operating conditions. A brief section on the medical use of high energy quanta takes the reader as far as he needs to get a proper grasp of the betatron, the synchrotron and the latest form of linear accelerator. It is for him to decide what biological warrant there is for the use of high energy quanta in the treatment of cancer, what he will get from Professor Mayneord is a full presentation of the facts from the physical standpoint.

Atlas of Obstetric Technic (2nd ed. London: Henry Kimpton 1949. Pp. 197. 52s. 6d.)—This book, by Dr Paul Titus of Pittsburgh, has gone through three reprints of the first edition in the last few years, and it will therefore be more appropriate to offer useful criticism than to recapitulate its good points. Some 200 of the illustrations deal with obstetrics, but a surprising number are concerned with what may be termed obstetric gynaecology. All are line drawings by Dr E. M. Shaekelford, and it is always easy to follow exactly what is meant. Notable omissions from the text are the manipulations necessary for the eventual delivery of the foetus lying transversely, or the almost impacted shoulder of a very large baby. Many small but helpful items in technique might have been included—the careful dissection of peritonium before the incision of the uterine muscle in caesarean section, or the introduction of sutures before episiotomy is done. Perhaps external pelvimetry might be deleted to make more room.

Biological Actions of Sex Hormones (2nd ed. London: Cambridge University Press 1949. Pp. 615. 42s.)—The first edition of this book by Mr Harold Burrows, F.R.S., was published in 1945, when such a competent review was very welcome, particularly to those returning from the pre-occupations of war time work. The new edition has been revised and is even more valuable. Throughout the essay, says the author, "literary daintiness has been held of second importance to clarity of statement", but the implied apology is superfluous, and the essay is an admirable contrast to those "reviews" which read like a series of excerpts from abstracts. Yet the book deals comprehensively with the great volume of experimental work on the actions of sex hormones particularly in mammals: it is well indexed and has a long bibliography. The subject is considered essentially from the laboratory point of view, with the human taking its place among other experimental animals, but a scientific background is provided for the clinician as well as perspective for the research worker.

THE LANCET

LONDON SATURDAY, DEC 2, 1950

The Second Premise

As our correspondence columns have shown, opinions differ widely on the proposed dismissal of hospital registrars. Our own have been based on three premises

- 1 The number of registrars in training for senior posts should not grossly exceed the number of likely vacancies
- 2 Except in a few specialties the only senior post open to a registrar is that of full consultant
- 3 A rapid increase in the number of consultant posts can no longer be expected.

If all three premises are valid, the Ministry's cut is inevitable: a great many registrars will have to go. Yet it is increasingly apparent that the National Health Service would thereby be damaged rather than improved. In the long run general practice would gain by absorbing some able men and women from the hospitals, but this advantage would, we believe, be more than offset by the loss to many hospitals through their departure, and the waste of much of their talent and training. No doubt some of their present work could be done by existing consultants, some by housemen, and some by clinical assistants, but much of it would not be done so well, or would not be done at all, for it is the presence of responsible trained registrars that has raised the standard of so many departments. In other words, the decision will positively downgrade the hospital service, and in present circumstances it will do little to upgrade general practice. If this is true—if the consequences of acting on our three premises are going to be bad—possibly there is something wrong with the premises themselves?

Apart perhaps from the registrars of St. Luke's Hospital, Bradford,¹ who declare themselves willing to face intensive competition leading to survival of the fittest, few have challenged our first premise—that the number of registrars in training should not grossly exceed the number of likely vacancies. This principle is accepted equally by the profession and by the Government, and will certainly be maintained. Our third premise has been widely and forcibly questioned, but we still think that, at a time when hospital building is approaching a standstill, it is unrealistic to suppose that the establishment of consultants can soon be brought up to the optimum contemplated in the Ministry's *Development of the Consultant Services*. The best hope of finding a practicable solution of the registrar problem lies rather, we suspect, in reconsidering the principle

embodied in our second premise—namely that (save in exceptional circumstances, where the appointment of a senior hospital medical officer is tolerated) there shall be no grade of hospital doctor intermediate between the senior registrar in training and the consultant enjoying full and final clinical responsibility. This principle was advanced by the profession, not by the Government, but many in the profession are beginning to wonder whether it is sound. Do not common sense and the needs of the service demand that many of the present registrars on completing their training period, should remain in hospital work as what Dr. MacWilliam² calls "assistant consultants"?

With his usual vigour and cogency, Dr. FFRANGCON ROBERTS in his letter this week points out that the situation has changed since the unplanned days when the number of consultants depended on the support of the fee-paying public, and he calls for a review of the new needs. Such a review would have to be rather more radical than that entrusted to the Spens Committee³ when it was asked to say what remuneration consultants and specialists should receive in a national medical service. The committee interpreted its brief widely, and was wise and far-seeing in its proposals for the livelihood of registrars as well as consultants, but it somehow ignored the fact that much hospital work can suitably be done by men and women who cannot be fairly classed as either. The unhappy sequel was that, in accepting the report, the Ministry of Health left everyone imagining that all specialists would be paid on Spens scales, and when, much later, it announced that many of them would be graded only as senior hospital medical officers, the profession as a whole resented what looked like an attempt to man the specialist services on the cheap. An uneasy compromise was reached when professional bodies persuaded the Ministry to confine the S.H.M.O. grade to specified specialties⁴ but the effect of this compromise is that many senior registrars, who are highly trained physicians, surgeons, or obstetricians though they have so far failed to secure a full consultant post, are now to be invited to leave the hospital service for general practice. Clearly this state of affairs, arising more from conflict than from objective planning demands the reconsideration for which Dr. ROBERTS appeals. The fact that a review of hospital medical establishments is even now in progress makes it all the more necessary that the Ministry, having deferred action so long, should stay its hand until the implications have been studied more closely.

At least one basic question has not yet been answered, or even perhaps posed, by the Ministry or the profession. Is it really advisable that full consultant status should be conferred, as the Spens Committee recommended, at the end of the training period—normally round about the age of 32? Unless a man is unusually talented and mature, this is an early age at which to take on the responsibilities which as Dr. ROBERTS says the word "consultant" ought to imply. One result of such early promotion is that consultant status lasts some 33 years, whereas registrar status—even including junior posts—lasts

² *Ibid.* Dec. 2, 1950, p. 714.

laws But apart from a few such highly debatable statements, the information given is accurate, and the book is a stimulating introduction to industrial medicine in its sociological aspects

Social Medicine

Editor LAGO GALDSTON, M.D. New York Commonwealth Fund 1949 Pp 204 \$2 75

THE high cost of medical care and the narrowness of current medical education led to the convening of a conference on social medicine as part of the centennial celebration of the New York Academy of Medicine. Such a representative gathering including inter alia, historians, physicians, public-health and nutrition experts, psychologists, and sociologists, expressed in corporate form the underlying conviction that "the days of monastery medicine and the ivory tower are gone." This book is a symposium of the papers contributed during the conference.

The early chapters are devoted to an excellent historical review of the changing relations between medicine and society since the days of Ancient Greece. The portrait of the evolution of social medicine is very clear. Though the individual contributions to the section dealing with the scope and objectives of social medicine are first rate, the picture as a whole is ill defined: too many varying definitions tend to confuse the reader. The chapters on epidemiology and nutrition are good, but the comprehensive account of the social applications of psychiatry is too weighty for easy assimilation.

The editor has succeeded reasonably well in the difficult task of welding so many individual contributions into a coherent whole. He has been helped to achieve this by the final contributor to the symposium who makes an eloquent plea for medicine to widen its sphere of interest by close association with the social sciences. Much physical and mental ill health could be prevented if the medical profession had a better understanding of the social relationship of man. In this respect undergraduate education is all important, for the good family doctor is a *sine qua non* in improving the health of the individual citizens who constitute the real wealth of the nation.

Die Gewebsmastzellen im menschlichen Knochenmark

P BREMY, Dr.med. Zurich. Stuttgart: Thieme 1950. Pp 78. D.M. 7 20.

THE mast cell has had relatively little attention from English writers. This volume reviews the literature on its origin, morphology, and distribution, and quotes work suggesting that its function is bound up with the production of heparin and possibly histamine. Mast-cell tumours have been encountered only in animals. In human subjects increase of the mast cells in the marrow is seen in severe infections, toxic conditions, amyloidosis, and after X-ray irradiation. Dr. Bremy presents 20 cases of his own, showing increased mast cells in the marrow, 5 were cases of anaemia due to tumours, 7 had aplastic anaemia, 1 had haemochromatosis, 3 had Marchiafava haemoglobinuria, and in 4 the origin of the anaemia was unknown. It is suggested that the increase of mast cells is a defence mechanism. The book is illustrated by a few unimpressive photomicrographs in monochrome.

Personality in Peptic Ulcer

A. J. SULLIVAN, M.D., head of the section of gastroenterology, Ochsner Clinic, T. E. McKEILL, M.D., member of the staff of the clinic, Springfield III. C. C. Thomas, Oxford. Blackwell Scientific Publications 1950. Pp 112. 21s. 6d.

ALL interested in peptic ulcer will enjoy reading this little book, written by physicians for physicians, and based on the observations of two gastroenterologists of the Ochsner Clinic, Tulane, who studied the psychic as well as the somatic aspects of something over 1000 peptic-ulcer patients. Their technique of establishing personality traits is simple and could readily be repeated. They recognise a main personality type which accounted for 72% of their patients, indeed the characteristics of this type, they say, can usually be demonstrated "in less than five minutes of questioning." They call the integrating drive in this behaviour pattern a "craving

for superiority," and are impressed by its "healthy" concern with solid achievement, for in its search for new goals it rides roughshod over all forms of self-indulgence, such as holiday-making, sleeping, and even eating. It is one thing to recognise a need for superiority but to raise it to the status of "a primordial urge for success" betrays an excess of zeal over prudence in the investigators. Their peptic-ulcer type is the extravert philistine who works at high pressure, talks big, admires skyscrapers, and thinks in terms of material achievement. American culture, rather than a "primordial urge," is at the back of this emphasis on, and concept of, success. This type of personality was absent in 11% of their patients, these had an underlying need to be fed and be taken care of, consistent with the psychoanalytic concept of peptic ulceration formulated by Franz Alexander. The book has a number of entertaining visual aids intended to fix the personality traits in a student's mind. The authors give illustrative case histories, and present a formula embracing the important variables of heredity, emotional situation, local trauma, and intrinsic gastroduodenal factors. They suggest that the relative value of each should be explored and treatment undertaken accordingly.

Some Applications of Nuclear Physics in Medicine

W. V. MAYNEORD, D.Sc., F.R.S. London. British Institute of Radiology. Suppl. no. 2. 1950. Pp 290. 35s.

THE chief applications here considered are those of beta-radioactive phosphorus, iodine, iron, and sodium, though cobalt comes in as a gamma ray source of growing importance. The radiologist will be fairly certain of getting the sort of information he needs, whether it be as a therapist or diagnostician, this applies not only to the actual nature of the substance in question and to the kind of radiation it emits, but also to the methods of dosimetry suitable to the operating conditions. A brief section on the medical use of high energy quanta takes the reader as far as he needs to get a proper grasp of the betatron, the synchrotron and the latest form of linear accelerator. It is for him to decide what biological warrant there is for the use of high-energy quanta in the treatment of cancer, what he will get from Professor Mayneord is a full presentation of the facts from the physical standpoint.

Atlas of Obstetric Technic (2nd ed. London: Henry Kimpton 1949. Pp 197. 52s. 6d.)—This book, by Dr. Paul Titus of Pittsburgh, has gone through three reprints of the first edition in the last few years and it will therefore be more appropriate to offer useful criticism than to recapitulate its good points. Some 200 of the illustrations deal with obstetrics, but a surprising number are concerned with what may be termed obstetric gynaecology. All are line drawings by Dr. E. M. Shackelford, and it is always easy to follow exactly what is meant. Notable omissions from the text are the manipulations necessary for the eventual delivery of the fetus lying transversely or the almost impacted shoulders of a very large baby. Many small but helpful items in technique might have been included—the careful dissection of peritoneum before the incision of the uterine muscle in caesarean section, or the introduction of sutures before episiotomy is done. Perhaps external pelvimetry might be deleted to make more room.

Biological Actions of Sex Hormones (2nd ed. London: Cambridge University Press 1949. Pp 615. 42s.)—The first edition of this book by Mr. Harold Burrows, F.R.C.S., was published in 1945, when such a competent review was very welcome, particularly to those returning from the pre-occupations of war time work. The new edition has been revised and is even more valuable. Throughout the essay, says the author "literary daintiness has been held of second importance to clarity of statement" but the implied apology is superfluous, and the "essay" is an admirable contrast to those "reviews" which read like a series of excerpts from abstracts. Yet the book deals comprehensively with the great volume of experimental work on the actions of sex hormones, particularly in mammals. It is well indexed and has a long bibliography. The subject is considered essentially from the laboratory point of view, with the human taking its place among other experimental animals but a scientific background is provided for the clinician as well as perspective for the research worker.

Surgical Relief of Angina Pectoris

THE surgical approach to angina pectoris has been mainly of three types. In the first the demands on the coronary circulation are decreased by lowering the basal metabolic rate. Some years ago total thyroidectomy was adopted for this purpose¹, but latterly hypothyroidism has been induced by thiouracil and its derivatives². In the second type of approach an attempt is made to revascularise the heart by attaching to its surface either omentum,³ muscle,⁴ or lung⁵ as a pedicle graft. Alternatively, anastomosis between the coronary end-arteries is promoted by applying to the surface of the heart foreign particles which evoke an inflammatory reaction⁶. Other measures said to increase the blood supply include occlusion of the coronary sinus,⁷ pericoronary neurectomy,⁸ and various forms of direct arterial anastomosis.⁹ In the third approach the afferent sympathetic pathways from the heart are divided, concurrent division of the efferent sympathetic fibres to produce vasodilatation, though probably less important, may improve the result. This third—neurosurgical—approach commands most attention, but sympathectomy has never become as popular in angina as in hypertension¹⁰ and peripheral vascular disease¹¹. This is not surprising in view of the poor prognosis for patients with angina, indeed with this condition the tendency is often to avoid any but the most pressing operations. With other diseases we at least hope that sympathectomy will improve the prognosis as well as relieving symptoms; with angina we can only hope that sympathectomy will make the patient's remaining days more comfortable.

The development of neurosurgical procedures for angina has followed, and contributed to, progress in our knowledge of the pain pathways from the heart. Most workers agree that the majority of pain fibres pass through the inferior cervical and the upper 3 or 4 thoracic sympathetic ganglia on both sides¹². From there they traverse the white rami communicantes and enter the spinal cord through the posterior roots of the corresponding segments. The rational procedures are therefore

1. Posterior rhizotomy, in which the upper 4 or 5 thoracic roots are divided on both sides. Some surgeons report most favourably on this procedure,^{13, 14} but others have been less fortunate.¹⁴

2. Paravertebral block with procaine¹⁵ or with alcohol.¹² The procaine method may give protracted relief. The alcohol method provides relief in about 80% of cases, but it carries an appreciable mortality-rate and has other disadvantages.

3. Cervicothoracic ganglionectomy, in which the stellate and upper thoracic sympathetic ganglia are removed on one or both sides. This has replaced the older operations in which various parts of the cervical chains alone were removed. WHITE and SMITHWICK¹⁶ and SJÖQVIST go down to T3 segment, while OLIVECRONA¹⁴ goes as low as T4 or T5. All these surgeons prefer the anterior¹⁷ to the posterior approach, for patients with angina do not tolerate the prone position. General anaesthesia is probably better than local, and the sympathetic chain should be well infiltrated with procaine before it is manipulated.¹⁸ Lighted retractors greatly reduce the difficulties of the operation.

LINDGREN¹⁹ has made a valuable study of the results in 105 cases, treated by cervicothoracic ganglionectomy in OLIVECRONA's (80 cases) and SJÖQVIST's (25 cases) clinics in Sweden, taking as controls 88 unoperated cases. Briefly her findings are these. The operative mortality was 8.5%, and the remote mortality-rate up to two years was the same in the operated as in the unoperated group. Three quarters of the patients had relief from pain on the side of the operation, and in two thirds the capacity for work was increased. More than half had a bilateral operation, performed first on the side where the pain was worst (usually the left), the two stages should be divided by an interval of at least two months. In a third of the patients migration of the pain towards the head took place after operation, and in 10% this vitiated the result. Relief of pain does not remove a "warning signal," for after operation all the patients had some residual pain or pain equivalent—the feeling of substernal oppression which accompanies the pain in the anginal syndrome was unaffected. On the other hand, the anxiety which many experience was greatly alleviated. The pulse rate was slowed after bilateral operations, but there was no effect on the blood-pressure or heart-volume, and no consistent effect on the electrocardiograph (E.C.G.) readings. Two troublesome complications were traumatic neuritis and nasal congestion. Taking account of all factors, a satisfactory result was achieved in over half the cases. LINDGREN suggests that the operation "should be reserved for a group of patients who, after an adequate period of observation, cannot be controlled effectively on a medical régime" (It may also be of value in certain cases of hypertension after thoracolumbar sympathectomy²⁰). It is contra-indicated in patients (a) with hypertension in whom myocardial infarction has been followed by a permanent drop in blood-pressure, (b) with an E.C.G. indicating myocardial damage combined with cardiac enlargement, and (c) with moderate or considerable cardiac insufficiency.

Judging by the results of operation, it seems that most clinicians are too conservative in the management of angina. We should like to see more of these operations performed in Britain and elsewhere, so that their value may be finally assessed. Paravertebral injections of alcohol cannot be regarded as a simpler and safer method of achieving the same result.¹⁸

about 7, and in practice this means that the consultants greatly outnumber their juniors in training. If registrars did no more than receive instruction, this numerical discrepancy would not matter, but they do many other things. Drawing a military parallel, Dr CHARLES HILL⁵ remarks that "a captain in the Army is not only training to be a colonel, he is at the same time doing a captain's work." Are we not in some danger of reproducing the inconveniences of an army in which there are more colonels than majors and company-commanders? Admittedly there are objections to doing advanced clinical work in a capacity that is even nominally subordinate. But the plain fact is that such work is being done satisfactorily by senior registrars all over the country, and it seems a little odd to tell them that they must forthwith stop doing it because, now that their training is over, our principles forbid us to offer them anything less than the consultant posts they cannot get. How deeply are these principles founded? Are they, actually, much more than a vigorous opposite reaction to the Ministry's unexpected and disappointing introduction of the S.H.M.O. grade? The crisis over the registrars may serve a useful purpose if it causes such questions to be asked. Until proved otherwise, this crisis should be regarded as a symptom of some underlying defect in our system, which needs to be exposed and corrected.

Some reduction in the number of registrars is desirable as well as inevitable, but the Ministry's drastic cut is neither the one nor the other. It might, we suggest, be avoided if the profession were to abandon its opposition to an intermediate grade between registrar and consultant. To posts in this grade, which would replace that of S.H.M.O. and might command comparable remuneration, men would be appointed competitively after finishing their registrar training. Under the title of assistant consultant, junior consultant, or (perhaps better) specialist, they would continue to work under the general supervision of a consultant, and as opportunity offered they would apply for consultant posts. Doubtless a few of the more brilliant would gain these as early as they do now, but the normal time of attaining consultant status would probably be nearer 40 than 32, and those who did not secure consultant appointments could if they wished go on doing their chosen work, without this recognition, to the end of their career. The time has come when the advantages and disadvantages of such an arrangement should be thoroughly debated. For our part, we hope that our second premise may prove to be removable.

Mass Radiography

It takes time to learn to handle a new tool, even when we are guided by experts. When the tool itself is new there are no experts, and those who use it must learn its possibilities together. Mass radiography is undoubtedly a tool of great value, but at the meeting of the Tuberculosis Association on Nov. 24 several speakers doubted whether we had yet discovered its proper purpose. Our hope has been to sift out from the general population those suffering from early tuberculosis or other serious chest disease and to ensure that they receive early treatment. That mass

radiography can in fact be used in this way is certain. Dr PETER KERLEY quoted as an example the 332 cases of active tuberculosis discovered by CLUTTERBUCK's unit at Glasgow, and followed up. These patients stayed on an average 6-7 months in hospital, and there were only 3 deaths among them, in a comparable control group the average stay in hospital was 18 months, and there were many more deaths. No one would attempt to belittle the importance of such results, but they must be seen in relation to the situation as a whole. The tuberculosis service needs much costly renovation: it lacks new quarters and equipment for the dispensaries and chest clinics, more beds, more staff. Mass radiography, as used at present, is expensive. Dr HOFFSTAEDT, whose contribution to the discussion we publish on another page, estimates that, using this method in an unselected population, the cost of finding a new case—that is, a case not already known to the clinics—may range from £11 to something like £109 (or, in exceptional circumstances, to more than £600), depending on the incidence rate and on the overhead expenses of the unit. Some feel that we should not be spending so much on finding new cases when we are not yet providing adequate treatment for those already found. Again, mass radiography can offer only a partial and incomplete contribution even to the task of case finding. At present we can only hope to survey about 7% of the general adult population yearly, and 80% or more of our case finding is still done by other methods. If we could survey the entire population annually it might be different, but, apart from the fact that this would occupy the time of far too many people, the cost would be prohibitive. Moreover, would an annual survey suffice? Often enough people are found to have tuberculosis, sometimes already cavitating, who a few months or weeks before gave a normal radiograph in a mass survey. Nor is diagnosis from a miniature—or indeed any other—film infallible, as various tests have shown.

These considerations all suggest that we are trying to use mass radiography in the wrong way. In the Newcastle region, as Dr HOFFSTAEDT tells us, there are plans for applying it only to industries and groups where a higher proportion of positives may be expected than in the general population. These include industries with a dust hazard, especially those employing young women, school leavers, school staff, and all others in regular contact with children, young people entering the Forces (among whom, as mass radiography has already shown, new cases are very likely to be found), prospective employees whose employers wish them to be examined, women attending antenatal clinics, chronic sick, suspects referred by doctors and chest clinics, contacts, and volunteers from the general population. These selected groups will provide plenty of work for the units, and must inevitably give a better yield of new cases than would equal numbers of unselected population. Suspected cases might well be sent for radiography on a 5 × 4 in. film of the type described by Dr OWEN CLARKE, and only those in whom the findings are positive might then need a full size film. Miniature radiography could in this way be used economically and effectively, thus perhaps releasing funds for use in other parts of the country's chest service.

use of protective measures can be ensured, and they hope the Ministry of National Insurance will give the Ministry of Health and the Department of Health for Scotland "every possible assistance to this end." More over, the Ministry might ask for a report, on each claim made, of what precautions had been taken or omitted by the claimant, and the establishment in which she or he had been employed.

Like others interested in this subject they have been impressed by the dearth of statistics showing the incidence of tuberculosis in different classes of the community, and they point out that statistics based on claims could be used to show the comparative incidence rates of the disease in particular industries and occupations. Those who have to find staff to nurse the tuberculous in sanatoria and chest hospitals have always feared that any public emphasis on the chances of infection might injure recruitment, but experience has proved that nurses are not deterred by risks they know and understand and against which they recognise that precautions are being taken. They are made much more uneasy by their own vague doubts and fears and those of their family and friends. When E. K. Geer,² in 1931, instituted rigid precautions in Ancker Hospital, St. Paul, he reminded patients and staff repeatedly that "eternal vigilance is the price of safety." He found that these precautions did not frighten nursing candidates off, but had just the opposite effect. Dr. Horace Joules, at the Central Middlesex Hospital, warns candidates and their parents that his nurses are expected to nurse tuberculosis, but explains the measures taken to protect them, and he never gets a refusal. The fact that the community is willing to recognise the risk, and compensate the nurse for taking it, may even help rather than hinder nursing recruitment.

The council recommended that the disease should be presumed to be due to the nature of the nurse's or health worker's employment unless the contrary is proved, and that the period of presumption should begin 6 weeks after entry into the work and end 2 years after the date of leaving it. One dissentient held that a year after the date of leaving would be adequate. The fact that other health workers are included gives equal privileges to doctors and others, who may also be exposed to risks of infection. The council deliberately confined themselves to tuberculosis, deferring any consideration of other communicable diseases until experience had been gained from this initial inquiry. The regulations are to be made as soon as they can be worked out with the health Departments.

FLUID BALANCE

THE record attendance at the Medical Society of London on Nov. 27 testified to the importance now generally attached to the balance of fluids and electrolytes in the body. Dr. H. L. Marriott opened the proceedings with a lucid account of the subject, which he has done so much to advance. About a ton of fluid passes in and out of the human body every year, he said, and yet its water-content in health remains remarkably constant. About five sevenths of the body water lies within the cells and the remainder is extracellular fluid (tissue fluid and plasma). Pitting oedema is usually evidence that at least a gallon of water has already accumulated in the tissue spaces owing to changes in intracapillary osmotic or hydrostatic pressure or to water and salt retention. (Edema due to hypoproteinaemia does not appear until the plasma proteins are grossly depleted and the body's reserves of mobile protein exhausted. Once present, it takes a long time to go, even on a high protein diet. powdered skimmed milk is a good source of protein, but the equivalent

of a bathful of milk may be required.' Dr. Marriott discussed the mechanical removal of oedema fluid, the indications for restriction of salt, the question of water intake, and the use of mercurial diuretics. Dehydration arises from insufficient intake of fluids or loss of alimentary secretions or sweat. If the fluid intake is inadequate, deficiency is essentially of water, and the osmotic pressure of the extracellular fluid rises, water passing out of the cells creates a sensation of thirst. If, on the other hand, the patient is losing bodily secretions—e.g., by diarrhoea or vomiting—deficiency is of water and salt, and his dehydration will not respond to ingestion of water alone. Salt depletion, said Dr. Marriott, is often missed, yet the type of dehydration present is easily determined by simply asking oneself the question—how has it arisen?

Dr. N. R. Lawrie reviewed the work of E. A. Schäfer and E. B. Verney on the rôle of the pituitary in the control of diuresis. Thanks to them, he said, it is now known that the posterior pituitary secretes an antidiuretic factor in response to changes in the osmotic pressure of the serum reaching it. This system is so sensitive that a change of 1% in osmotic pressure leads to a 1000% change in renal excretion. The hormones of the supra-renal cortex are also concerned in the retention of sodium chloride, and so of fluid, since more sodium is retained than chloride, the administration of these steroids may lead to alkalosis as well as oedema. In the discussion, Sir Heneage Ogilvie observed that soldiers are taught to manage on a very small water ration, and expressed the view that some of the mortality among the wounded during the war could be attributed to dehydration. Mr. Dickson Wright deprecated the excessive use of the intravenous route, when he went round his wards at night and took down the houseman's drips he felt that he was doing a useful piece of work. Dr. F. Avery Jones thought that the potassium ion was not receiving the attention it deserved. The traditional meat extracts, he said, are rich in this essential factor, but if the patient cannot take anything by mouth, potassium may be added to infusion fluids. Dr. Marriott agreed that potassium is an "up and coming" ion, but it can also be a dangerous ion, especially if renal function is poor.

A working knowledge of the theoretical background of fluid balance has become essential to every practising surgeon. The distinction between the two types of dehydration—water depletion and salt depletion—is particularly important, though both may of course be present at the same time. As Dr. Marriott pointed out, a consideration of the cause of the condition may tell us which form we are dealing with. On the chemical side, the serum sodium level is the only certain guide (as Dr. D. A. K. Black remarked in the lecture summarised on p. 778), but estimation of urinary chloride will often help. With the invasion of the hospitals by pure science, pathology laboratories are being submerged with requests for estimations of unequal value to the patients. But the measurement of the urinary chlorides can frequently facilitate the rational treatment of postoperative vomiting without adding to the pathologist's burden, for Fantus's test, performed in the side room, will usually help in the decision as to whether saline is indicated or not. If the house surgeon does this simple test himself, he need have no compunction in asking the clinical pathologist to estimate the serum potassium in selected patients. Possibly soon many hospitals may have facilities for rapid estimation of sodium and potassium by flame spectrophotometry.^{1,2} Elaboration of data will make even greater the need for increased study and understanding by clinicians of the problems of fluid balance.

Annotations

CHLORAMPHENICOL ON PRESCRIPTION

As reported on p 759, chloramphenicol ('Chloromycetin') is now manufactured in this country in sufficient quantity for it to be dispensed on prescription. This antibiotic is the only one which is produced by synthesis on a commercial scale. It is given by mouth, but because of its extremely bitter taste must be taken in capsule form, it is not suitable for parenteral injection. A number of infections which are resistant to penicillin and streptomycin respond to chloramphenicol—namely, the enteric fevers, rickettsial diseases (including Q fever), virus infections of the lymphogranuloma—psittacosis group, atypical (virus) pneumonia, and acute brucellosis. These are the main therapeutic indications for the new antibiotic. In addition it is of value in urinary tract infections due to penicillin-resistant or sulphonamide-resistant strains of *Bact. coli*, proteus, *Staphylococcus pyogenes*, and *Strep. faecalis*, it is less effective against *Pseudomonas pyocyanea*. Chloramphenicol should be used with discretion in urinary tract infections, careful search for underlying obstruction should be made in all cases. For controlling the infection alkali therapy or sulphonamides are the treatment of choice, in the acute cases which fail to respond, sensitivity to sulphonamides, penicillin, streptomycin, and chloramphenicol should be tested and treatment given accordingly.

Chloramphenicol has a considerable antibacterial action against flora of the respiratory and intestinal tracts. Preliminary reports suggest that it may be beneficial in whooping cough, this problem requires further investigation and trials are being carried out at a number of centres in this country. With an adequate oral dose chloramphenicol reaches therapeutic levels in the cerebrospinal fluid, and very satisfactory results have been reported in *Haemophilus influenzae* meningitis. Serious toxic effects are rare though granulopenia has been reported.¹ Anorexia, nausea, and looseness of the stools are not infrequent, glossitis, stomatitis, pharyngitis, and proctitis occasionally develop and seem to be due to yeast infection. These complications usually clear-up rapidly when the drug is stopped.

Chloramphenicol is the first of the new oral antibiotics to be released. Experience has shown that in this country there are a few, but only a few, diseases resistant to penicillin and sulphonamides for which its value is clearly established. In our admiration for the new specific remedies we are apt to overlook their cost, particularly when this is included in a national rather than a personal budget. Moreover, the newer the remedy, the higher the price. One week's treatment with sulphonamides or penicillin costs approximately 10s., six days' treatment with chloramphenicol costs £10 at current prices. From every point of view therefore it is in the best interests of the patient that treatment with the newer antibiotics should, wherever possible, be subject to strict bacteriological control.

MECHANICAL HEART AND LUNGS

THORACIC surgeons have long dreamed of a machine which will take over the duties of the heart and lungs while they are operating on these vital organs. Gradually their dream is approaching fulfilment, and many hospitals throughout the world—the Sabbatsberg in Stockholm, for example, and Hammersmith Hospital here in London—have mechanical heart lungs working efficiently.

Hitherto, mechanical heart lungs have been used solely to supply oxygenated blood to the brain, but in

Philadelphia, after years of experiment, Gibbon¹ has completely diverted the dog's blood stream from both venae cavae and successfully returned it to the circulation. Four dogs are still alive and well 8–10 months after having their blood stream diverted in this manner for 30–46 minutes. In Stockholm, Björk² has devised an apparatus in which a series of revolving plates are partly immersed in a trough of blood in an atmosphere of oxygen, this allows an oxygen uptake of about 130 ml. per minute with a blood flow of 800 ml. per minute, so it seems to be somewhat more efficient than the method of Gibbon which introduces up to 70 ml. of oxygen per minute.

The difficulties of applying these methods to man remain formidable. The patient's blood must be heparinised, and the machine requires preliminary priming with compatible blood. Insertion of the cannulae is likely to raise further difficulties. In the dog, Gibbon has ingeniously reached the superior vena cava through the stump of the azygos vein, and the inferior vena cava through the right auricular appendage. This technique necessitates an approach through the right side of the chest, and in operations on the mitral valve, for example, the burden of bilateral thoracotomy might prove too heavy for the average patient. Nevertheless, Stokes and Gibbon have taken us another step towards the ultimate goal.

TUBERCULOSIS AND HEALTH WORKERS

NURSES who acquired tuberculosis in the course of their work were, until recently, likely to experience much hardship. No special provision was made for their care or maintenance, and many of them ended their lives almost in penury. Since the introduction of larger tuberculosis allowances such extreme hardship has disappeared, but the position of nurses differs from that of others who acquire tuberculosis in that they usually enter nursing training during their most susceptible years, and are exposed to greater risk of tuberculous infection than people in other walks of life. There is no doubt that they can be very largely protected from this added risk by special precautions to safeguard their health, or that, if they acquire it, they stand a good chance in most hospitals of being treated early and successfully. These, indeed, are proper objects at which every hospital should aim. Moreover every hospital should see to it that nurses are fully reabled, preferably on full pay. But there are still hospitals which fail in these duties. The decision of Dr Edith Summerskill to insure, under the National Insurance (Industrial Injuries) Act, nurses and other health workers in close and frequent contact with tuberculosis infection, though a welcome if tardy, recognition of the nurse's special risks, must in no sense be regarded as a substitute for proper standards of care. (Court³ found that "the risk of contracting tuberculosis is significantly greater for nurses in most general hospitals than for other professional women of the same age".)

The Minister based her decision on a report,⁴ just published, by the Industrial Injuries Council, under the chairmanship of Sir Wilfrid Garrett. The council had in mind the great disparity between the standards of precautionary measures in different hospitals, and frankly declared "there is little prospect of a close approach in the near future to ideal conditions in all the hospitals concerned." But they evidently felt that to prescribe tuberculosis as an industrial disease might well hasten rather than retard a general levelling up. Claims might be reduced effectively, they hold, if a wider

ment in the film *Another Case of Poisoning* gave effective warning of the dangers of handling food carelessly, and in *His Fighting Chance* showed how the patients' chances of recovery from poliomyelitis have improved. Two specialist films were also made for doctors and nurses—one on bronchography and the other on infection in hospitals.

THE BLAIR BELL MEDALLIST

A GREAT and well deserved honour was paid to Prof J M Munro Kerr on St Andrew's night when the obstetrical section of the Royal Society of Medicine made him the first recipient of its Blair Bell medal, which is to be awarded quinquennially to the man or woman who has done most to advance the science of obstetrics and gynaecology. Mr V B Green-Armytage, president of the section, said that for over fifty years Professor Munro Kerr has adorned and embellished his profession and speciality "for over fifty years he has, as you know, fired and enthused countless students and postgraduates, and, still more, for over fifty years he has certainly earned the love, affection, and regard of countless of our colleagues." After being introduced by Mr Green-Armytage and Prof Hilda Lloyd, F.R.C.O.G., Professor Munro Kerr received his medal at the hands of Lord Webb-Johnson, president of the society, and concluded a happy occasion with a happy speech recalling old friends and former days.

"CITIES WITHOUT NOISE"

WHEN Elizabeth Barrett Browning complained that the world was 'full of dreary noises' she can have had no inkling of the din which was destined to rend the air of the 20th century. We who live in the age of motor cycles, pneumatic drills, and neighbours' wireless sets may well regret the passing of a time when noises were nothing worse than dreary. From excess of visual impressions we can shut our tired eyes, but our ears are never closed, and through them, day and night, we are exposed to noises against which we can offer no defence.

In addressing the Royal Society of Arts on this subject on Nov. 29, Lord Horder spoke as chairman of the Noise Abatement League, and as one who has played a prominent part in its labours. Its most tangible achievement before the war, he said, was the law on night silence in built up areas, the effects of which were soon felt in daylight as well—and are still, as anyone who knew London twenty years ago can testify today. But the enthusiastic enemies of noise (who included H G Wells, A P Herbert, E V Lucas, and others of their calibre) had many irons in the fire: their sensitive ears could distinguish in the cacophony of the metropolitan orchestra such discordant instruments as the steel riveter, the ageing tramcar, the milk cart, and the dustbin—and they fought them all.

The root of the matter, said Lord Horder, is spacing. If we spread ourselves over a sufficient area we cease to offend each other with our noises: if we gather too closely together the result is mutual discomfort. The happy mean is a problem for the architects, who have often shown their interest in this work. Noisy industries should be zoned, and high buildings alternate with lower ones, school playgrounds should not occupy confined spaces, and airports should be sited so that aircraft need not cross the city. Noises in the home also deserve attention, and some people might be prepared to pay a little more for insulated rooms at present (as H G Wells once said) flat-dwellers are about as protected from sounds as they would be from sights if the walls were made of glass.

We must not imagine, Lord Horder continued, that all noise can be prevented: some, it seems, must be

endured: the pneumatic drill, for instance, cannot be silenced without losing most of its power. All the more reason, then, to suppress such noises as we can. We tolerate the blended hum of street traffic, but the roar of an unsilenced motor accelerating down the street jolts our senses and affronts our sensibility. Science, it is true, has made us noisy, but it has also given us the weapons to subdue noise, if we will only use them. Those who want to make a really unholy din should do so in the proper place—in a park, perhaps, like Whipsnade, provided for their use. "The elimination of needless noise," Lord Horder concluded, "will never be achieved by Acts of Parliament alone—no, nor by science, however firmly we may harness it to this particular purpose. It can only come about by a general recognition of the fact that needless noise is a form of selfishness and lack of thought. Thus it is the man in the street who must, eventually, decide if we shall have 'Cities without Noise'. He must get it into his head that making a noise that is not necessary is a form of bad manners."

THE DURHAM DISPUTE

TRADE unionists commonly insist that their fellow workers should join their union by forcing employers to dismiss anyone who does not do so, they successfully apply the policy of the closed shop. The idea is that no worker ought to benefit from the efforts of a union unless he supports it by becoming a member, and this is certainly a tenable point of view. The situation is altogether different, as the *Times* points out,¹ when it is the employer who insists on membership of a union against the wishes not only of the workers but also of the union concerned. That is what the Durham County Council is doing: it has decided that all who work for it must be members of an approved trade union or professional organisation, and it intends to discharge anyone who does not produce evidence of membership. Though most of the 48 doctors working for the council are, no doubt, members of professional organisations, at least 44 of them have rightly decided that this demand—made without negotiation on the national level—is unacceptable. And the British Medical Association, so far from wishing to receive new members under the council's compulsion, is giving full aid to the objectors. The Royal College of Nursing and also the union which represents most of the 4000 teachers in County Durham are taking the same line, and the Government has unsympathetically hunted to the council that if dismissal of teachers and doctors leads to a breakdown of its medical and educational services, central grants towards these services will no longer be payable. The council has a good record and its members are no doubt acting from sincere conviction, but, as often happens when people's loyalties are narrow, it is managing to do a great deal of harm.

Prof E D ADRIAN, O.M., F.R.C.P., has been elected president of the Royal Society in succession to Sir Robert Robinson, who retires after five years in office.

Through his work at the Home Office as an expert on drugs and factory legislation, Sir MALCOLM DELEVINGNE was brought into contact with many members of the medical profession. He represented the British Government at international conferences on labour regulation and on the control of opium. In 1931 he was chairman of the supervisory body for the limitation of manufacture of dangerous drugs. When he retired from the Civil Service in 1932 he was nominated by the Privy Council as a member of the council of the Pharmaceutical Society. In 1936 he was chairman of the Interdepartmental Committee on the Rehabilitation of People Injured by Accidents, and three years later he presided over the Emergency Committee for the Nursing Profession. He died on Nov. 30 at the age of 82.

THE DOCTOR AND ATOMIC WARFARE

MAN's tolerance of adversity, is always greater in the event than in the forecast, during the late war civilians in Britain—and in other countries as well—shouldered calmly a far greater burden of anxiety and hurt than had been thought possible without disintegration of the social structure. No doubt the same would happen in the even more dangerous conditions of a new war. But in the future, as in the past, to tolerate is not enough; our inclination, and our duty, is to survive, and the best hope of surviving the strange new dangers we shall face lies in learning what is known of them. Thus the editors of the *Practitioner* have done well to publish this month a symposium on the medical aspects of atomic warfare. Among other things this disposes of the contention that physical preparation is futile, it is estimated that with a Nagasaki type bomb among a population of density 43 per acre, if everyone were in houses deaths would number 31,100 and injured 29,500, but if every one were in a reinforced brick surface shelter deaths would be 14,300 and injured 10,500. However, preparation does not end with the construction of shelters, much would depend on intelligent action by the public. As Sir Ernest Rock Carling (who has advised on the symposium) remarks in his article on morale: "Safety will be chiefly in behaviour, and behaviour can be learned so thoroughly as to become instinctive." Here our profession has a large share of the responsibility, for "medical men are better able than others to appreciate the risks, and should know what can be done to avoid them or to mitigate their results. No one, perhaps, is in a better position to inculcate the right attitude of the people to danger."

EXPLOSIONS IN THE OPERATING-THEATRE

WHEN Dr H J V Morton ignited 20% cyclopropane in oxygen at the Royal Society of Medicine on Dec 1, he provided the members of the anaesthetics section with a practical demonstration which they will not quickly forget, and when a succession of speakers described the innumerable sources of heat in a theatre, and the inflammability of almost every known anaesthetic mixture, their hearers must have wondered how they had survived long enough to attend the meeting at all. However, the comparative rarity of explosions in the operating-theatre cannot justify the neglect of precautions, these are accidents which can and must be prevented.

In his presidential address, Dr Alexander Low pointed out that long continued storage of ether (particularly in sunlight) leads to the production of peroxides which enhance its inflammability—and this includes its use for sterilising skin. It explodes more violently in nitrous oxide and oxygen than in pure oxygen, he said, and is safest of all in air. Cyclopropane is generally used in a closed circuit in this country, and it diffuses safely from a small leak unless there is a source of heat within one foot, but the stomach can easily come to contain an explosive quantity. Dr Low then considered the sources of heat in a theatre. The use of electricity involves not only the danger of sparks, but also of heat production owing to overloading, dry batteries are safer than mains transformers. Static electricity can be generated in many ways—by sweeping a dry blanket over a rubber mattress, by the passage of gas through rubber tubing, and so on—and the only sure safeguard is the use of conducting rubber and the provision of conductors which lead away the charges to earth. Non-electrical sources of heat include sterilisers, candles, lamps, hot air syringes—and cigarettes!

Several speakers had personal experience of explosions and fires, and told hair-raising stories of the ways in

which they were caused. One explosion was the result of propping a cylinder full of gas against a hot radiator; another should have occurred, but apparently never did, in a nursing home where the Ministry regulations were hung above the naked jet of a geyser in the theatre.

Dr Low described at some length the precautions which should be observed in the ideal theatre: they may be laborious, but they are well worth while. Sources of heat are more easily controlled than explosive mixtures, but neither should be neglected. The universal use of conducting rubber in the theatre¹ is one of the most effective steps that can be taken to eliminate "static"—which even in our damp climate is the greatest danger. The floor must be a good conductor, and to it all apparatus and every person in the theatre (including the patient) should be properly earthed. Trolley wheels should be fitted with conducting rubber tyres, or be replaced by metal castors. Other equipment should be provided with drag chains of unpainted metal links.² Other sources of heat are more obvious and so less dangerous, but all electric fittings and switches should be continually checked by the electricians, and even minor faults remedied immediately. Finally, the prevention of faults in the anaesthetics apparatus is the responsibility of the anaesthetist, who must of course be fully acquainted with the mechanics of his machine, as well as with the inflammability of every gas and every mixture with which he works.

PAY IN THE FORCES

FOR some time the British Medical Association has been negotiating for improved pay of doctors in the Services, and last week the Minister of Defence announced new rates, which appear on p 776 of this issue. Broadly speaking, the remuneration of general duty officers now compares fairly with average incomes in civilian work, but the rates for specialists do not. The greatest need of the R A M C is for more specialists, and the new rates promise no permanent relief from the unsatisfactory situation in which the Service advertised for civilian specialists to serve for limited periods on specially attractive terms.

AN INFORMATIVE YEAR

TODAY the administrator is more and more dependent on a reliable information service which will tell him how the statutory instrument which seemed so clear and comprehensive in Whitehall strikes the capricious realists in the queue at the food office. The Ministry of Health has been quick to realise how much help they can get in their new responsibilities from the Central Office of Information.³ A Survey of Sickness has been made every month for the Registrar General, and a special inquiry into schoolboy diets was made for the Ministry of Health. This showed that schoolboys in the poorer sections of the population today had diets as good as middle class children before the war. The C O I has also helped the Ministry in its campaign to secure the immunisation of children against diphtheria. Last year about £30,000 was spent on press and poster advertising, but at a cost of £40 per case of diphtheria the sustained campaign is now helping to save up to £2 million in one year, for the notifications of diphtheria have fallen from 55,000 to 5000 during the past ten years. The campaign for the prevention and treatment of venereal disease also continued, and the campaign for blood donors raised their numbers to nearly 378,000 as against 108,000 at the end of 1946. The Health Depart-

in system the response was 52-78%, while with the contracting out system it was 74-84%. In other words, people do not care to say they are unwilling. On the other hand, even the contracting out system may get a poor response if other factors interfere, thus of all the pregnant women attending antenatal clinics in Newcastle who were booked for radiography (contracting-out system) only 60% attended. They will bring their children to the welfare clinics, because they get good advice and vitamin supplements, but they are less ready to interrupt their daily chores to go and be investigated for a disease they have no reason to think they have acquired.

LIMITATIONS OF MASS RADIOGRAPHY

The contribution of mass radiography to case discovery is on the whole modest. Of all the new cases on the register of a big urban chest clinic in 1949, only 18.5% had been discovered by this method, and in a random sample of the population in a sanatorium only 33 (20%) of 162 men had been found by mass radiography. It is worth noting that of these 33, no less than 14—nearly half—had been picked out by mass radiography shortly after joining the Forces. In a random sample of 145 patients in the same sanatorium in 1947, the proportion picked up by mass radiography was only 11%. In another sanatorium, in 1949, 15 out of 104 women, and 11 out of 70 men had been found in this way (15% in both cases), but again nearly half of the men so discovered had been picked up in the Forces.

In any case mass radiography of the total population on a voluntary basis cannot even be attempted. The units and personnel at our disposal cannot deal with more than a small fraction of the adult population. One unit can manage 25,000-30,000 miniature films a year. In Region I, with a population of over 2,700,000, five units are now operating. Average samples from a rural district and a large town indicate that 72.5% of the people in the region are aged 15 or more, and the adult population can therefore be reckoned as 2,110,000. The five units

TABLE III—RESULTS OF SURVEYS CARRIED OUT ON THE PREMISES OF FIVE LARGE FACTORIES

Factory	Attended %	Suspected %	Discovery rate* %
A	60	22	0.55
B	75	18	0.45
C	60	147	0.37
D	53	14	0.35
E	37	11	0.25

*Discovery rates reckoned as 25% of the cases referred to the clinic or kept under observation (of table I)

can deal in a year with only 150,000 people, or 7% of the adult population of the region.

SUGGESTED USE OF MASS RADIOGRAPHY

In this region it is intended that routine surveys should be made in hazardous industries, especially dusty occupations like mining, sand blasting, and steel dressing, in industries and factories known to have an unusually high incidence of tuberculosis, such as tobacco and clothing factories, especially those employing young women, and in any factory or workshop in which an unusual proportion of employees are known to have developed tuberculosis.

In addition, it is proposed that there shall be quarterly sessions at every main centre of population, at which the following groups would be regularly examined:

- 1 All school leavers and any other school-child referred by the school medical officer or the family doctor

- 2 Teachers, school kitchen staff and all others in regular contact with children (e.g., kindergarten and nursery school staff, and staff of welfare clinics)
- 3 All young people of both sexes about to enter the Forces. (This could be arranged in collaboration with the Ministry of Labour and National Service)
- 4 Prospective candidates for employment, at the request of their firm or employing body (e.g., the Civil Service)
- 5 Women attending antenatal clinics
- 6 Chronic sick, and all suspects with symptoms, sent by family doctors, factory doctors, or medical officers of health.
- 7 Patients referred from chest clinics
- 8 Contacts, for regular examination and follow up. (This would be arranged on behalf of and in collaboration with the chest clinics)
- 9 Volunteers from the general population who wish to be examined

I believe that by keeping to these groups we could use mass radiography much more effectively and economically than we are doing at present.

My thanks are due to Dr F. L. Wollaston, Dr W. H. Dickinson, and the organising secretaries of the Durham and Newcastle Unit, and to the staff of the Newcastle Regional Hospital Board, who kindly supplied the material on which this paper is based.

MINIATURE RADIOGRAPHY WITH 4 × 5 INCH CUT FILM

OWEN CLARKE

M.A., M.D. Camb.

SENIOR MEDICAL REGISTRAR, PAPWORTH SANATORIUM

MINIATURE radiography had been under consideration for many years before the late war. D'Abreu (1945) has described his own earlier work in France and Brazil, and Bentley and Leitner (1940) were also experimenting in this country, but it was the war which provided the urgent spur to more rapid development of techniques. Trail (1942), Trail et al (1944), and Brooks (1944a) were the leaders of progress in the British Services, and when the U.S.A. came into the war there was a wide demand in America for routine chest radiography before enlistment. The purposes of miniature radiography in both countries were essentially the same—to avoid the intake of tuberculous people into the Services, and by routine examination of Service personnel to detect cases of pulmonary tuberculosis as early as possible.

After the war, development was directed towards the survey of civilian populations, and once again the emphasis was on quantity and on speed of operation. Individuality was not considered important. In a report to the Medical Research Council, Clark et al (1945) considered the relative merits of 35 mm film and the 4 × 5 in. stereoscopic films which had proved so popular in the U.S.A., and they decided in favour of the smaller film. It was generally agreed that in skilled hands the technical results were equally good and for civilian mass radiography the 35 mm film 'had the added advantages of mobility of apparatus, larger numbers of examinations in a shorter time, and much more rapid processing and interpretation' (loc. cit. p. 2). There is also the advantage of compactness in storage with 35 mm.

These factors are important for mass miniature radiography, quite different considerations arise when miniature radiography is to be a part of clinical and preventive medicine, divorced from the urgency and routine of a mass survey. In Britain only 35 mm. roll film has so far been obtainable, and all attention has been focused on mass surveys, but the technical efficiency has developed to such a high standard that we should now consider the use of miniature photo

ASSISTANT CHIEF PHYSICIAN, HOLLYWOOD HALL SANATORIUM,
WOLVINGHAM, DURHAM

The following figures, based on the work done by mass radiography units in Region 1 during 1949, give some idea of the cost of case finding by this method. Four units were in action, three of them completely mobile and independent, and they took between them 97,250 miniature films during the year. When all the expenses of running the units are taken into account the average cost per miniature film works out at 1s. 6d. Cases sent for further investigation, as a result of suspicious findings in the miniature film, numbered 6247, or 6.4% of the total examined. Large films taken of these cases worked out at a cost of 4s. 8s. 10d. each.

The incidence rate of pulmonary tuberculosis discovered by mass radiography seldom exceeds 2%. Under the figure of 4s. 6d. as the cost of a miniature film it is possible to calculate the cost of discovery of a single active case of pulmonary tuberculosis at different incidence rates, as follows:

Incidence rate %	Cost per case discovered s. d.
0.15	41 10
0.1	56 6
0.5	15 0
1.0	22 10
1.5	11 17
2.0	11 6

There would be the costs in an average survey, but it is possible to find extreme examples where the cost per case discovered is much higher, as in the following:

Over a period of 2½ months an area with an adult population of 54,700 was surveyed. The total number who volunteered for examination was 2415, or 0.04% of the population. Of these, 41 (1.5% of the number examined) were referred to the clinic for further examination, and 9 cases of pulmonary tuberculosis were found among them; but 7 of these were

*Based on a communication to the Tuberculosis Association on Nov. 24.

TABLE 1—COST ANALYSIS OF CASES EXAMINED BY UNIT "N" IN 1949

Type of survey	No. examined A	No. referred to clinic B	New active cases found C
1. Routine surveys of factories, &c. (combined with open sessions to general public (volunteers))	24,174	(0.72% of A)	(26.1% of B) (0.18% of A)
Cost per case discovered £10d.			
2. (a) Contactment by local doctors (b) Contactment by chest clinics (including contacts)	(8% of grand total)	(6.8% of A)	(40.5% of B) (2.16% of A)
Cost per case discovered £8 4s. 10d.			
3. Grand total of 1 and 2	25,158	(1.1% of A)	(31.7% of B) (0.16% of A)
Cost per case discovered £14 7s.			

known already to the clinic. Only 4 were active cases, and 2 of these were already on the register; so the survey revealed 2 new active cases which had been unknown before. The cost of the survey was £1261, giving a cost per single examination of 10s. 6d., the cost per patient referred to the clinic was £37, and the cost per newly discovered case of active tuberculosis £632.

Table 1 compares the discovery rates (and their cost) in routine surveys, in factories and elsewhere, with the discovery rates in surveys where the cases were selected as suspicious by doctors or chest clinics. It will be seen that the cost per case discovered is £8 4s. 10d. where suspected cases only are examined, as against £10d. when unselected populations are surveyed. In this particular survey the average cost per miniature film worked out at 3s. 10d.

For comparison, the figures from another unit (unit "D") may be considered. In this unit the overhead expenses were somewhat higher than those of unit "N," the cost per miniature film in 1949 working out at 1s. 9d. Unit "D" had an average discovery rate for all cases of 0.07%, the cost per

TABLE 2—ANALYSIS OF RESULTS WITH DIFFERENT GROUPS OF PEOPLE EXAMINED IN NEWCASTLE IN 1949 (UNIT "N")

Group examined	Referred to clinic or kept under observation D	Estimated discovery rate (active cases) % of total E	1/2 as % age of D
1. Routine surveys of factories, stores, offices, &c.	0.5-2.0	0.12-0.5	25
2. School children	0.0-1.0	0.0-0.25	25
3. Sessions open to general public (volunteers)	2.5	1.0	40
4. Referred by doctors and clinics, contacts	6.0	2.4	40

active case discovered being £35 12s. At sessions open to the general public the discovery rate was 1%, and the cost per active case found £21 15s.

It will be seen from Table 1 that the discovery rate, as might be expected, was lower in routine surveys and open sessions than in selected cases sent by doctors or clinics. Table 2, which gives the discovery rates of unit "N" with four different groups, emphasises this point. When large numbers of supposedly healthy people are examined (as in routine surveys) the discovery rate is low. At open sessions for the public it is somewhat higher because those who are anxious about their health are more likely to attend than others, and the group is therefore self-selected. Among people referred by doctors and clinics, the discovery rate is naturally still higher. Table 2 shows not only that the discovery rate was higher in groups 3 and 4 (the selected groups) but that a higher proportion of those kept under observation or referred to the clinic from these groups turned out to have tuberculosis than was the case with groups 1 and 2.

SOME FACTORS AFFECTING RESPONSE

Table 3 shows one of the weaknesses of unselected surveys. In five large factories the discovery rate fell as the response fell. (Only one factory (factory A) lies outside this pattern, possibly there was contact infection, or some other special cause, to account for this discrepancy.) Bradbury¹ made a similar observation in 1948.

Response to an offer of mass radiography examination varies, among other things, with the way the offer is made. If candidates are asked to attend if they wish (to contract in) the response is always poorer than if they are asked to say they will not attend (to contract out). Thus Sheffield unit found that with the contracting

¹ Bradbury, J. C. S. *Lancet* 1948, II, 203.

Teaching—These films are very convenient for circulating among a small audience, and for students to copy, or have printed, for personal records

Marking—Miniature films should automatically have the name, date, and unit included on them, thereby avoiding dark room confusion and saving subsequent laborious clerical work. The incorporation of a photo-electric timer ensures uniformity of quality and allows comparatively inexperienced staff to attain standard results

CLINICAL USE

Sanatorium and Thoracic Units—Initial diagnosis requires full size films, but much of the subsequent control can be done with 4 × 5 in film. Pneumo-thorax control would be simplified, since it would be no extravagance for junior physicians to keep a permanent record of screening appearances. All follow up records and investigation of contacts can be done on small film

General Hospitals—Many proposals have been made for routine chest examination of outpatients, and in Canada the 4 × 5 in film is widely used for this purpose. It would not be necessary to process all of these at once, except for a chest clinic, and in most cases a report could be added to outpatient notes. The film would be available at subsequent visits if required. Other purposes to which this type of film could be put in hospitals are the routine examination of staff and the examination of tuberculosis contacts

Public health Work—Emphasis has recently been laid on the desirability of routine chest radiographs of immigrants. This is already obligatory for U.S.A. and Canada, and the speed and simplicity of miniature cut film has been described elsewhere (Clarke 1950)

Non thoracic Conditions—The use of miniature photo fluorography need not be confined to chest conditions. I have used it to locate foreign bodies in the hand and forearm, and for injuries of the upper limb and similar conditions, and have found that it is thereby easy to obtain a convenient and accurate record and to achieve considerable economy in cost of film. Experience might well reveal many other examples in which the use of this material would be both beneficial and economical

EQUIPMENT

The apparatus used by the Ontario Immigration Department in London was a Newton Victor set KX12, designed for full-size films, 70 mm camera, and 4 × 5 in. cut film. That set is not available in this country

What is required is the stand, screen, tunnel, lens, and cassette holder to operate in conjunction with the usual hospital X ray tube, or with a separate tube for that purpose. The mounting and base plate of the tunnel should be designed to take either a roll film camera or 4 × 5 in cut film, so that the more convenient unit may be used for each specific job

It may be possible to modify the present standard 35 mm set to take the necessary lens for 4 × 5 in film. If not, the separate stand must be produced

In the past the difficulty has been the larger lens necessary and the slightly more cumbersome equipment. If miniature radiography is to develop for general clinical use, and not only for mass survey work, British firms must produce the lens and develop this type of set, and film of the necessary quality must be available in this country. Then, and only then, will it be possible for all hospitals and clinics to appreciate the great value of this technique

SUMMARY

Miniature radiography need not be confined to mass survey work, it could play an important part in general clinical medicine

For this purpose the following conditions must be met (1) individual negatives are necessary (roll film is impractical), (2) rapid processing must be possible, so that the X ray film can be read at the same session, (3) the film must be large enough to be read without projection or special apparatus, and (4) the detail must be accurate enough to allow a clinical opinion to be formed, occasional control by full size film may be desirable, but is not essential

Experience with more than 25,000 films has shown that the 4 × 5 in cut film fulfils these conditions, and offers advantages over other types in economy, convenience, and accuracy

British firms should supply the equipment needed for the wider development of this technique

DISTRIBUTION OF CHLORAMPHENICOL

ANNOUNCEMENT BY THE MINISTRY OF HEALTH

Owing to improvement in supplies, chloramphenicol ('Chloromycetin') will be generally available on prescription from Dec 11. The following provisional lists are intended as a guide to practitioners in prescribing this antibiotic

There are certain infections (list 1 below) in the treatment of which chloramphenicol is more effective than any of the therapeutic agents at present generally available. Apart from these there is a variety of infective conditions (list 2 below) in which the value of treatment is less certain, preliminary trials both in this country and abroad have given variable results, and further experience is needed before chloramphenicol can be recommended as routine treatment in these diseases. In certain diseases (list 3 below) there is no satisfactory evidence that chloramphenicol has any therapeutic value

- Infections in which the therapeutic value of chloramphenicol is superior to that of sulphonamides or penicillin**
 Typhoid and paratyphoid fevers (excepting carriers)
 Brucellosis (undulant fever)
 Rickettsial diseases (i.e., typhus, scrub typhus, Q fever)
 Psittacosis
 Lymphogranuloma inguinale
 Atypical (virus) pneumonias
 Urinary tract infections resistant to sulphonamides and penicillin. (These include infections due to resistant strains of *B. coli*, *B. proteus*, *Ps. pyocyanea*, and *Str. faecalis*. Sensitivity of the organism to chloramphenicol should be determined.)
- Infections in which therapeutic benefit from chloramphenicol has been reported but not fully substantiated**
 Whooping-cough
 Salmonella food poisoning
H. influenzae meningitis

fluorography for general radiological purposes in hospitals and clinics

The 4 × 5 in cut film has been widely used throughout the U.S.A. and Canada but is almost unknown here. My experience in London is based on 25,000 X ray films taken for the Ontario Immigration Department in 1948-49. In my view this size of film possesses such outstanding advantages that it should be the film of choice for further development throughout the British Isles. Except for survey work, the 4 × 5 in cut film is preferable to roll film for photofluorography for many reasons, and it also has many advantages over full size film for clinical purposes. It is, however, first necessary to be confident of the technical quality of the film.

COMPARISON OF RESULTS

Hilleboe and Morgan (1945a) studied and compared the results with 14 × 17 in celluloid film and the various miniature photofluorographic films—e.g., 4 × 5 in cut film and 70 mm and 35 mm roll film. They tested these films for resolving power, detail, contrast coefficient, and relative sharpness, and in each case the 4 × 5 in film was found to be inferior only to the full size celluloid film and was superior to the smaller types of roll film. They held the same view as was expressed in the M.R.C. report (Clark et al 1945)—that the 35 mm roll film was most suitable for mass surveys—but they considered that the 4 × 5 in cut film was preferable for small numbers. Although they used both single and stereoscopic 4 × 5 in films, the advantage of the latter was "insignificantly small and of little value" (Hilleboe and Morgan 1945b), but might increase if small films were developed for diagnostic purposes.

This preference for the 4 × 5 in cut film has been emphasised by many workers—e.g., Clark (1942), de Lorimier (1942), Cranch (1943), Havlicek and Gill (1941), and Brooks (1944b). Tice (1946) surveyed more than 1700 civilians by both 70 mm and 4 × 5 in films, and his comment is directly relevant to the consideration of future development: "In the 70 mm. film we sacrifice specialisation for speed in the 4 × 5 in film we reverse the process and stress individualisation."

Those who have experience of 35 mm mass miniature radiography in this country know that the results show a high degree of accuracy compared with full size films, reports from U.S.A. and Canada confirm that in skilled hands the 4 × 5 in film is of even better quality. Frailek et al (1947) report 98.3% accuracy at the Gage Clinic, Toronto, and Plunkett et al (1941) confirm that the 4 × 5 in film gives greater detail. My own experience supports this view. In the accompanying illustration a contact print made direct from one of these negatives shows the actual size of the film but cannot show the high quality of reproduction attained.

ADVANTAGES OF 4 × 5 IN CUT FILM

If it is accepted that the technical standard is adequate, this film has two very valuable advantages over full size film—economy and convenience for storage. Compared with the miniature roll films it has the great advantage of rapid individual processing so that a film can be taken and examined at the same session, and each patient's films can be kept together in one envelope with his case notes. The film therefore combines many of the advantages of full size and miniature material, and if it were introduced into general X ray work it would prove most useful.

Economy—Each film costs about 4d compared with 2s 8d for each 15 × 12 in film. For fifty exposures the saving is therefore about £5, and a busy department could easily save £1000 a year by using this miniature size for routine work and for follow up of cases. Its use need not be confined to chest work, since any case in which the patient can be radiographed erect could be controlled by this method.

Individual films allow records to be kept together with the case notes.

Speed of processing enables the miniature film to be read at the same session, this is essential for chest clinics and routine follow up of out patients.

Storage and Reference—The 4 × 5 in films can be kept with the notes or in separate storage rooms. The space occupied is less than a tenth of that occupied by full size films, and by storing in boxes of 100 films reference is made easier. 1000 full size films weigh about 90 lb and occupy 4 c ft, whereas 1000 4 × 5 in films weigh about 9 lb and occupy 1/4 c ft. A series of films are easily handled for comparison of progress.

Viewing by Direct Vision—Enlarging or projection is not necessary, and the wet film can be viewed directly against a window or a viewing box. Clark and Poulsson (1941) have shown that accuracy in reading this size of film is easily acquired.

Reproductions or Extra Copies—Extra negatives can easily be made at little cost, and they should be a routine on discharge of a patient. Reports can be accompanied by an actual X ray picture instead of an inaccurate and vague attempt at a drawing. Prints can easily be made by direct contact. Lantern slides require an intermediate negative on fine grain film, the technique of which is simple and within the capability of any X ray department but 4 × 5 in films can be projected directly in a lantern.

Contact print made direct from 4 × 5 in cut film (actual size)

GENERAL MEDICAL COUNCIL

SESSION NOV 28-DEC 2

After hearing the President's address, reported last week, the council considered a heavy calendar of penal business

Disciplinary Cases

The council did not direct the Registrar to erase from the Register the name of *Mrs Ethel Grundy Toward*, registered as of Brookside, Durham Road, Birtley, co Durham, M B Durh (1925), who appeared for postponed judgment

John William Paterson Collier, registered as of Holm Lea, Church Road, Yapton, Sussex, M B Edin (1922), was charged with having called at or about 12 20 A M on April 9, 1949, at the house of Gladys May Hitchman to attend an infant, when under the influence of alcohol to such an extent that his professional judgment was impaired. Information in the case was received from the Minister of Health. Mr Harold Brown, instructed by the solicitors to the council, presented the facts and Dr Collier was represented by Mr Gerald Howard, K.C., M.P., and Mr J MacGregor, instructed by Messrs Hempsons, on behalf of the Medical and Dental Defence Union of Scotland

Consideration of this case had been postponed at the May sitting owing to the illness of the district nurse who was to have given evidence. Opening the case at the present session, Mr Brown stated that the nurse now refused to give evidence.

Mr Herbert Hitchman said that he and his wife were on the list of Dr Collier. On April 7, 1949 his wife was delivered of a male child. Dr Collier was in attendance. On the evening of April 8, his wife and he noticed that the baby looked "very sick." Soon afterwards the district nurse examined the baby, and asked Mr Hitchman to telephone to the doctor. After several calls he was told at 11 30 P.M. that the doctor had been contacted at Bognor and was on his way. Dr Collier arrived about 12 15 A.M. and, said witness, "he looked very the worse for drink." After Dr Collier left, the nurse told witness to telephone Dr Collier's partner, who came about 1 A.M. The baby was then dead. Mr Hitchman afterwards communicated with the executive council for East Sussex. Witness agreed that Dr Collier still attended his family, and that Dr Collier normally had a fairly high colour and was abrupt in his talking and movements.

Mrs Gladys May Hitchman examined, said that when Dr Collier came, after midnight, he staggered into the room, and flopped on to the bed. "Just by looking at him you could tell he had been drinking." The way he examined the baby did not seem right. He tapped the baby's chest. Asked what Dr Collier said after the examination, witness replied "He said it was perfectly all right." He wiped his hand round the nurse's face and said "That's all right, nurse."

The first witness for the respondent was his host at the party at Bognor. There was nothing in Dr Collier's behaviour, the witness said to suggest he was drunk. When he was called away he came to witness to apologise because he had had an urgent call and had to go. Two other guests said that there was nothing about Dr Collier on this evening to suggest he was the worse for drink.

Dr Collier in the witness box, said he saw the child at birth and on the following morning when he made a full examination. Mrs Hickman whose first baby had died, was extremely worried about this infant who was premature. He made a careful examination not because the child appeared ill but because he seemed weak, he found nothing clinically wrong. In the evening the baby was blue and breathless, but apparently no more ill than when he saw him in the morning. Describing his method of examining the chest he said he used the method of alternate percussion on fingers and the chest which Sir Robert Philip had taught him to use in young children. When he heard that the child had died he was not surprised because it was a sickly, premature baby. He had no recollection of rubbing his hand over the nurse's face. He gave the cause of death on the death certificate as congenital atelectasis. Cross-examined, he said that he was not surprised at the baby's death but he did not expect it to be sudden. He did not tell anybody in the house that it might be imminent. He told the nurse that he could find nothing wrong with the baby. He did not know that the nurse had sent for his partner until he had heard the evidence. In reply to a member of the council who asked why he gave a death certificate if he could not find anything wrong on clinical examination, Dr Collier replied that he gave a post-mortem differential diagnosis.

The council found the facts alleged against Dr Collier not proved to their satisfaction

AN "UNEXPECTED VERDICT"

A doctor was charged with having been convicted in 1949 of committing an act of gross indecency with a 14 year-old boy, for which he was sentenced to 12 months' imprisonment. Mr Winterbotham presented the facts and the doctor was represented by Mr Harold Brown, instructed by Messrs Freeman & Son.

During the hearing Mr Brown recalled that it was held in the Spackman case that the council could not go behind a conviction, but this was not an ordinary case. As the Lord Chief Justice had said, in judgment in the Court of Criminal Appeal, the trial judge would have preferred a verdict of acquittal. Giving sentence he had said "I do not agree with that verdict and I do not understand it." Mr Brown submitted that even if the council could not go behind the conviction, if they were presented merely with the bald fact of the conviction, they would be incompletely armed with the relevant facts. If, for instance, in a trial there were gross irregularities and an appeal was not put forward, he did not think the council would be debarred from going into those circumstances. He submitted that the surrounding circumstances were a matter for the consideration of the council.

The family of the boy, Mr Brown said, had continued as patients of the doctor for months afterwards and neither parent said a word to him. As the judge had said "Can you believe the parents believed that boy's story?" When the matter came before the Court of Appeal the Lord Chief Justice thought it so important that he ordered it be heard before a full court of five judges. The appeal was dismissed on the grounds that the court could not interfere with the verdict of the jury.

The boy had not been treated by the doctor, though he was on the doctor's list. The point might arise on some occasion whether being on a doctor's list constituted a professional relationship. Mr Brown submitted that there must be something more.

When the doctor gave evidence, Mr Brown said he wished to ask him whether he was in fact guilty, but the legal assessor advised the council to rule against the question. Mr Brown then asked if the doctor had at all times maintained his innocence. "I have," he replied. Since his release he had resumed practice in the same district, and now had 1600 patients on his list. The boy had not been on his list but on his partner's. Evidence of character was given by a colleague who had been a fellow student, and by two patients.

The council found that the doctor had been convicted of the misdemeanour, but did not direct the Registrar to erase his name from the register.

The council directed the Registrar to erase the name of *Iltyd Gwyn Williams*, registered as of Ravenscourt, Tynwydd Road Barry, Glamorganshire, M B Edin (1923). He was found to have had intercourse with a woman (the complainant) when he stood in professional relationship with her.

ALLEGED CANVASSING

Eugene Wlodzimierz Collis registered as of 183, Woodstock Road, Oxford M D Vlna (1937) appeared before the council on two charges of canvassing. Dr Collis had bought the house but not the practice, of Dr Harper, of Oldbury.

The first charge alleged that he canvassed patients of the practice of Dr G G Cooke of Oldbury and the second alleged that he canvassed patients of the practice of Dr Jack Lookley, Dr Reginald Morris Howson, and Dr Hazem Barrada. The complainants in the case were Dr Howson and Dr Barrada.

Mr Benjamin Sadler gave evidence that last December he wanted glasses. At the time he was registered with Dr Harper and he went to Dr Harper's surgery, where he saw Dr Collis. Witness admitted that he went to that house because that was where Dr Harper lived.

Sir Sydney Smith. Did the doctor say that you could not get glasses from him unless your wife also was put on his list? — No.

Mr Benjamin Griffiths said that he went to Dr Harper's surgery when he had flu. He had been a patient of Dr Harper all his life. He found Dr Collis there, who examined him and said he was the new doctor. Witness asked if he could be put on Dr Collis's list and he said "Yes certainly." He did not know until he got home that his family were

3 Infections in which there is no satisfactory evidence of the therapeutic value of chloramphenicol

Influenza

Common cold

Polomyelitis and poliomyelitis

Tuberculosis

Syphilis

Ulcerative colitis

Chloramphenicol is probably effective in a number of pyogenic infections, such as bacterial pneumonias, gonorrhoea, and peritonitis, but it is doubtful whether it is as effective as penicillin or sulphonamides. In bacterial endocarditis due to organisms which are penicillin resistant, chloramphenicol is probably inferior to a combination of streptomycin and penicillin. An exception to this is bacterial endocarditis due to penicillin-resistant *Staph. pyogenes*, for this, as for any severe penicillin resistant staphylococcal infection, 'Aureomycin' is the antibiotic of choice.

It should be noted that chloramphenicol in the powdered form has an extremely bitter taste. It is not, therefore, easily administered to young children who will not swallow capsules.

MEDICINE AND THE 1951 FESTIVAL OF BRITAIN

LAURENCE DOPSON

On the South Bank exhibition site, the pavilions are now taking recognisable shape in preparation for the opening of the Festival next May. The site is divided by the arches of Hungerford Bridge, but the two sequences of buildings thus formed are to tell different parts of the same story. The theme of the whole is Britain's contribution to civilisation, past, present, and future, particularly as seen in science, technology, and industrial design. Within that theme the exhibits in the up stream section, west of Hungerford Bridge, will be concerned with The Land, or the environment which has influenced and in turn been influenced by British contributions. The exhibits in the down stream sequence between Hungerford Bridge and Waterloo Bridge, will deal with The People—i.e., with what the British people have achieved. Medical contributions take their place where appropriate in both sequences. Thus British contributions to tropical medicine, biology, and some aspects of physiology are to be included in the Dome of Discovery, which will be devoted to British exploration and discovery in all fields—terrestrial, oceanic, geological, physical. The more personal aspects, such as the work of Harvey and others on the circulation of the blood, are featured in a pavilion in the down-stream sequence where the general theme of health is illustrated.

A council has been formed to advise the Festival Organisation on the proper representation of British achievements in science and technology, and one of the members is Dr H. P. Himsforth, Secretary of the Medical Research Council. A medical sciences advisory panel has also been set up, and Sir Sheldon Dudley, F.R.S., has acted as medical adviser. The executive officer for the health section is Mr N. B. Clayton.

HEALTH PAVILION

In the Health Pavilion which stands partly under Waterloo Bridge, the theme will be the health of the individual and the health of the community. As he goes in, the visitor will find an introductory section describing the body and its functions. For instance, the explanation of the nervous system given here, and the contributions of such men as Sherrington, will help the lay visitor to understand the later section on neurology. Similarly, the section on physiology of the blood which begins with Harvey's discovery of the circulation, will provide a link to succeeding sections.

In the introductory section, the general description of nutrition will prepare the visitor for the next part, on the maintenance of health, where, as an example of applied nutrition, will be illustrated community feeding as developed in Britain in the late war. The public health services, in which the British sanitary reformers led the way, will mainly be shown in relation to clean water supply and sanitation, but there will also be a small exhibit on air hygiene and the prevention of atmospheric pollution. In this way the two aspects of health are exemplified—the individual by good diet, the community by public health measures. Mass immunisation, biological standardisation, and vital statistics will also be illustrated.

Turning from health to sickness, the visitor will learn something of Britain's contribution to therapeutics, to neurology, and cardiology, and this section will lead him naturally to the next—the introduction to surgery. Here he will be shown how modern surgery depends on asepsis and anaesthesia, based on the work of such men as Lister and Simpson. Blood transfusion and the work of the National Blood Transfusion Service will also be explained, and the visitor will learn something of the part that Britain has played in developing thoracic, orthopaedic, and plastic surgery. He will be shown how burns are treated today according to British practice in asepsis, and this will link back through the danger of infection, to air hygiene. Through the exhibition there will be stimulating cross references of this kind, to show how the story of health and disease is interrelated.

The survey of surgery will be interrupted to tell the story of nursing. Here the Nightingale tradition of treating the patient as a person and of concern for the comfort of the patient, which is characteristic of British nursing, will be emphasised.

The importance of environment to health is further demonstrated in the section on homes, which will emphasise the family unit, and on school buildings.

OTHER SCIENTIFIC EXHIBITIONS

As a corollary to the South Bank exhibition, an exhibition of science will be held on the ground floor and basement of what will afterwards be the new west wing of the Science Museum in South Kensington. Here, as at the South Bank exhibition, modern methods of presentation will be used. The exhibition will not be arranged in conventional museum fashion, with small specimens laid out on benches and in glass cases. Written explanations will be cut to a minimum, and the displays will be largely visual and three dimensional. The main theme will be the spirit of scientific discovery and recent advances in knowledge of the structure of matter and fundamental processes. There will, for example, be models showing the structure of sugars, fats, and proteins, and models and photographs to demonstrate cellular formation and differentiation. A final section will be devoted to current research. Some medical exhibits, inappropriate to the South Bank exhibition will be found here. Cancer research, for instance, is included in the exhibit showing the structure of matter.

In the specially converted aircraft carrier *Campania*, a small travelling version of the South Bank exhibition, including the health section, will tour the ports and seaside towns of the United Kingdom.

All these exhibitions are designed for the intelligent lay public. The specialist will also be catered for by the appropriate learned body. The Royal Society of Medicine, for instance, is arranging for visiting doctors a series of addresses appropriate to the Festival theme during the summer of 1951, and medical museums in London will probably be staging special exhibitions. The British Association has arranged that its 1951 meeting in Edinburgh shall form part of the Festival.

charged with having been convicted at the Tower Bridge magistrates' court on March 13, 1950, of receiving two suitcases knowing the same to have been stolen, for which he was fined £20 and £10 10s costs. The council's solicitor presented the facts, and the respondent was represented by Mr N Leigh Taylor of Hempsons, solicitors, instructed by the Medical Defence Union.

In evidence, Dr Sack said that to control nervousness and excitability he had been in the habit of taking 'Sodium amytal' at first 3 g a day. On the day in question he took 24 g. He had visited the offices of the Medical Defence Union in the afternoon, and Dr Robert Forbes, the secretary, gave evidence that he had made a note at the time of Dr Sack's visit that his demeanour appeared to be that of someone under the influence of a drug. He was now quite different. Mrs Sack said that her husband was now quite free from any influence of drugs, and a certificate from Dr G W B James under whose care he was admitted to hospital for treatment after the conviction, was read.

After consideration in camera, the President said the council found the conviction proved, but had decided to postpone judgment for a year.

William Melrose, registered as of 15, St Paul's Square, Liverpool, L.R.C.P.E. (1924), was charged with having been convicted at Liverpool City magistrates' court on July 14, 1950, of being found drunk for which he was fined 10s. After consideration in camera, the president announced that the council found the conviction proved. This was not the first time respondent had appeared before them, and they were bound to take a serious view of a further conviction. Judgment was postponed for two years.

RESTORATIONS

The president announced that the Registrar had been directed to restore to the Register the names of *Gerald Donagh Flitley*, *Henry Charles Coutts Hackney*, and *William Hamilton*.

Business of Council

The President introduced the report of the Pharmacopœia Committee, of which he was appointed chairman in place of the late Professor Dilling. The British Pharmacopœia Commission, 1948-53, had, he said, unanimously recommended that the main titles of the monographs in the 1953 *British Pharmacopœia* should be stated in English.

"It is proposed that Latin titles should not be coined for new monographs. It is also proposed to alter the sequence of the monographs by placing preparations such as tablets, injections, and tinctures immediately after the parent substance, instead of grouping the preparations on a pharmaceutical basis, such as *Tabellæ*, *Injectiones*, and *Tinctura*."

In view of these proposed changes, the Commission thought that the monographs in the *Addendum* dealing with preparations of human blood should appear as a separate section with titles in English. "It is felt that no useful purpose would be served by inventing Latin titles for these monographs."

An extra sitting of the council, to consider disciplinary and other business, including educational, will be held in February, 1951.

Disabilities

55 FRACTURE OF THE SPINE

It all came of trying to help with the chores. I had just finished dressing and was going down to the kitchen when my foot slipped on the top of four steps. Involuntarily I jerked my whole body forward, and in the split second that I was suspended in mid air I felt a terrific rending and crunching sensation right across my middle. As I collapsed in a heap at the bottom I knew beyond the slightest question that I had fractured my spine. I was frightened to death. Could I move my toes? Well—I knew I'd got to face the music sooner or later, and it had better be now. I tried to waggle them. They waggled. That was one of the best moments of my life. By this time my son was enjoying a good laugh at my expense and my wife had arrived on the scene.

"I've done it this time," I said. "I've fractured my spine. But it's all right. I think you'd better call the ambulance." Then I passed out.

When I came to, I was cold and drenched with sweat. The doctor from next door was bending over me, he went, gladly enough, to invite an orthopaedic colleague to come round. The others gave me a hot water bottle and heaped rugs on me. My resuscitation was fairly rapid, and with it came a curious sense of well being so that I felt inclined to get up and welcome my visitor at the door. But I lay where I was, wondering whether I ought to be turned on my face or my back. The ambulance was already waiting when the orthopaedic surgeon arrived. "Never mind," he said, "we'll soon get you to the hospital and see what you've done." There was no room in the little lobby where I lay for the ambulance men to do a textbook lift. They heaved me up, a little unceremoniously I thought, and turned me on my back on to a stretcher with a rolled up blanket across its middle. But as long as I was conscious and my back muscles were all in a good state of spasm it probably didn't matter.

At the hospital I was taken straight to the X-ray department where they were waiting to receive me. The radiographer wasn't worried by fractured spines. "Now turn on your side," she said as cheerfully as if I had nothing worse than a pint of bismuth inside me

and like a lamb I turned. Soon afterwards the radio logist appeared from the dark-room. "You're quite right," he said. "It's the body of D12 that's gone, but it's quite a good position." And with that I was taken to the ward and put to bed with a hard pillow under my middle.

Hours passed. My exultation was over, and I was beginning to feel under the weather again. I thought of my days as a casualty officer when I had reduced all manner of fractures, fixed the limbs in cumbersome splints, and sent the victims home without so much as an aspirin. My remorse grew on me. If only I'd done this before I had that job, how different my behaviour would have been, I'd have treated my patients and not only their fractures. Just then the medical superintendent came in. "Are you comfortable?" he asked. "Well, I suppose I am," I replied, "if you're using the word in the hospital sense." He took the hint, and in a few minutes a nurse came along and gave me an injection. The hours passed but I lost count of them, and at last the nurse came and gave me another injection and off I went to the plaster room. There I was arranged with my chin on one table and my shins on another while a trolley supported my middle. My torso was adorned with straps of felt, and when all was ready the surgeon said, "Now, I want you to hang on just like that when we take the trolley away." I dug my elbows into the front table, off went the trolley, bang went a slab of warm wet plaster into the small of my back, and in an instant three pairs of hands were bandaging, rubbing, and slapping plaster all round me. It all seemed to be over in an incredibly short time, and then I was helped to my feet and one of the girls trimmed me up and cut a window in the front. They took me back to the ward and left me to dry with an electric cradle over me.

What happened after that I never really knew. I remember vomiting from time to time—a difficult thing to do decently when you are lying flat and cannot move. In the intervals I felt I was cooking slowly, but for the greater part of the time I did not know what was going on, either because I fainted again or because I fell into a drugged stupor. But there was no stupor about me next morning. Indeed I was only too wide awake, and the next three days were a positive nightmare of a well

registered with Dr Barrada. His wife went up to Dr Collis and told him, and Dr Collis said "That's all right. I've bought Dr Harper's business, and it's only right I should have you."

Mrs Cutler said that she was a patient of Dr Barrada. Her husband had been a patient of Dr Harper, and she went to Dr Harper's surgery and asked Dr Collis to call. Dr Collis said "Why not have one doctor?" She thought he wanted her on his list. When she later gave him only her husband's card, he said "Just the one?" and she said "Yes."

Mrs Fletcher said that her baby was on the list of Dr Barrada. Dr Barrada said he could not circumcise the baby privately unless it was transferred to some other doctor's panel, and she arranged to have the child put on Dr Collis's list. In reply to Sir Sydney Smith, witness said Dr Collis did not ask her directly to have her name placed on his list, but he said that if they were satisfied with the way he had treated baby, and she and her husband wanted to change, they would have to sign the form.

Dr Collis, in evidence, said that he put an advertisement in the *British Medical Journal*, as a result of which he purchased Dr Harper's house. Nearby was the house of Dr Cooke, who was carrying on the practice. Subsequently Dr Cooke told him that he wanted to retire and that his partner saw no objection to Dr Collis taking over the practice. Witness had a conversation with the chairman of the executive council, who said he saw no reason why he should not succeed to Dr Cooke's practice, but that he was to treat this conversation as confidential and should not say anything of it to Dr Cooke or his partner. Dr Collis formally applied to take over the practice and received a letter from the clerk to the executive council, as a result of which he engaged an assistant and got a car. Mr Griffiths told the witness he was a patient of Dr Harper's, and was Dr Collis Dr Harper's successor? Witness said that he was not. Mr Griffiths said he wanted to be on Dr Collis's panel. Asked by his counsel whether he ever tried to persuade Mrs Cutler to come on his list, Dr Collis replied "On the contrary. She asked me several times, and several times I sent her back to her own doctor."

In answer to Sir Henry Cohen, Dr Collis said that, having started from scratch, he now had a list of 1800 patients. Oldbury was a small place. When Sir Henry asked if it was likely, in view of the proximity of the other practitioners, that it was from those practices that his patients would have come in some numbers, Dr Collis replied "Yes, it is likely."

After deliberation in camera the president announced that the council had found the facts not proved to their satisfaction.

"GESTAPO METHODS"

Florence Joseph O'Driscoll, registered as of 43, Moss Lane Liverpool, M.B.N.U. (1928), appeared before the council charged with infamous conduct in that

'On May 31 1950 you were so far under the influence of drink that you were incapable of properly carrying out your professional duties towards your patients who were waiting to consult you at your surgery, at 43 Moss Lane Liverpool and in particular were incapable of rendering any proper and necessary treatment to Mrs Doreen Shone one of the said patients.'

Information in the case was received from the Chief Constable of Liverpool. Dr O'Driscoll was represented by Mr D. Braben, Mr Howard, K.C., M.P., and Mr MacGregor instructed by the council's solicitors, appeared to state the facts. Mr Howard, opening the case said that Mrs Shone was not present, and the only evidence would be that of two police officers.

Inspector James Smale said that on May 31 in response to a telephone message he and Detective Sergeant Alfred Metcalf went to 43 Moss Lane Liverpool. The door was answered by the doctor's brother, who said the doctor was seeing no more patients. Witness explained that they wanted to see the doctor privately. He stopped the brother from closing the door, and the doctor came to the surgery door. He was leaning on the casing to support himself. When witness told the doctor of the complaint Dr O'Driscoll said "Let's be having some names." When the inspector replied that he was not in a position to give the name, the doctor said some thing of which witness caught the word "Gestapo." His breath "smelt of spirits." The inspector said he would like to see his brother. Dr O'Driscoll said his brother was not in. The officers went upstairs and found the brother standing

on the landing. Told that he should see no more patients, Dr O'Driscoll said "I will always take good advice." He asked the two men in the waiting room to leave, and then the officers left. Cross examined, witness agreed that his notes were sketchy. Asked if it was right that he or the sergeant looked through the waiting room window, witness replied it would have been impossible to do so. He agreed that he asked the doctor his age, whether he was the tenant of the house, whether he was married. The doctor's answers were all "thought over." He did not ask the doctor how many drinks he had had. "I could see he had had too many." Inspector Smale agreed, in reply to the Legal Assessor, that if no complaint about dangerous drugs had been received, he had no right to go into the house. Witness told Sir Henry Cohen that the doctor had seemed "bemused." Sir Henry pointed out that he asked for the name of the complainant, which was reasonable.

Detective Sergeant Metcalf, in evidence, said the doctor adopted an "aggressive manner." He produced his pencil "with a flourish" and said "Let's be having some names." He considered the doctor was under the influence of drink and was unfit to deal with patients. Cross-examined, witness said the inspector did look into the waiting room window before they went into the house. Asked about what right he had to be in the house, witness agreed that they were on "rather delicate ground," but "We were never told we couldn't come in."

Dr O'Driscoll, in evidence, said that Mrs Shone was a panel patient to whom he was giving antenatal treatment. When she came to his surgery on the night in question, he called her Mrs Davenport in error, Mrs Davenport was another patient, also pregnant, who lived at the same address. He apologised. Describing what happened when the police officers visited him, Dr O'Driscoll said that when the detective sergeant suggested he should close the surgery he refused. When they said they wanted to see his brother, he called him, and getting no answer, said "He has apparently gone out, you can look for yourself." He told the police he had had one drink of beer that day. He thought the officers had forced themselves into the house, and to justify themselves were going to make out the charge of drunkenness. In answer to Sir Henry Cohen, Dr O'Driscoll said his surgery had been open from 5.30 to 7 P.M., and he had seen about a dozen patients. "Had you any complaints from those patients?"—"None whatever."

Mr R. W. Varning, a school teacher, said he and another man were in the doctor's waiting room, and he saw the plain clothes man look into the window. The officers left before he did. There was no smell from the doctor, and there was nothing about him to indicate that he was not sober. He gave witness a prescription, which witness read without difficulty. Dr Joseph Mackin gave evidence of having visited Dr O'Driscoll on the same evening and having noted that he was perfectly sober. Dr O'Driscoll's married stepdaughter also said that the doctor was quite sober.

Mr Braben addressed the council on behalf of Dr O'Driscoll, and Mr Howard said he did not wish to reply. After consideration in camera for only about a minute, the President announced the council had found the facts alleged not proved to their satisfaction.

ADDICTION OFFENCES

Nigel Harold Maurice Russell Monro, registered as of 442, Nell Gwynn House, Sloane Avenue, London, S.W.3, M.B.S. (1936), was charged with having been fined £20 at Ashford Magistrates' court in 1947 for offences concerning failure to enter dangerous drugs in a register with being fined for insulting behaviour and assaulting a police constable later in 1947 in London, with having been convicted on July 11, 1949, of being drunk and disorderly and assaulting a police constable, and of having been convicted at the Central Criminal Court in November, 1949, of occasioning bodily harm to Wendy Joan Monro, for which he was sentenced to twelve months imprisonment. Mr Winterbotham stated the facts of the cases, and said that the Home Office had withdrawn Dr Monro's licence to obtain drugs. After deliberation in camera the President announced that the council had found the convictions proved, but in view of the testimonies from his patients they had decided to postpone judgment for two years.

Eric Leonard Neil Shorten Sack, registered as of 64 Trinity Court, Gray's Inn Road, London W.C.1, M.B. Ox. (1945), was

In England Now

A Running Commentary by Peripatetic Correspondents

My friend the psychologist has just bought a radio-gram (No, no! I don't mean an X-ray film—a wireless phonograph) She may not be able to mend a fuse but she is au fait with the latest work on electronic brains, so she approached her new companion with more respect than many people would have given it. It had one of those automatic record changers and she found it a little upsetting after her previous homely one with its broken handle and unpredictable clockwork. The music-click-whirr-plop-whirr-music sequence hunted at a considerable amount of thoughtful effort inside, and she used to sit trembling with anxiety after each side ended, wondering how long this dark-skinned monster would be content to crouch in its corner whurring, clicking, and plopping in the right order.

Last week the inevitable happened. The machine took a fancy to the beginning of the second movement of the Eroica. It played the passage through and then began again. The sad music boomed ominously round the flat. Then to her horror it began for the third time. What was she to do? Should she become a dominant mother figure and whack the machine on its flank? Or perhaps stroke it and try to develop a transference? Eventually she decided to emulate Fabre with his wasp and let it go on for seventy-five (or was it a hundred and seventy-five?) times to see if it would learn. The fifth rendering saw her own nerves in no good shape, but being a good psychologist she clenched her teeth and carried on. Soon after this the machine got really obsessional and its needle stuck in a groove. Compulsive outbursts were obviously only a matter of time, so she packed a bag and spent the night at the hospital. Now she is in a sorry plight. She would like to phone her flat, but who—or what—might answer?

I know the answer to the flying saucer problem. It came to me when I read an article by Mr. Fred Hoyle saying that relativity would enable us to travel in a high-speed rocket for a month by rocket time and return to find the earth several thousand years older by earth-time. Obviously the saucers do not come from another planet at all but from our own. Ages ago, when science had got a bit further on than we are now, some people set out in saucers for a month's pleasure cruise in space. Soon afterwards the people left behind blew themselves up with atom bombs. Then civilisation began again, and now the saucers have just got back. So far they haven't landed, but when they do get a good look at their children they will certainly beat it, at the speed of light, for another million years. So I have packed a suitcase and if I see a strange blue light in the sky I shall thumb a lift.

If *The Men* had been made by Ealing Studios there would perhaps be more laughs in it, and, paradoxically, it would be more moving. Somehow we have a better knack of putting across the semi-documentary film than the Americans. Stanley Kramer has set his picture in a genuine hospital for soldiers with paraplegia and has been scrupulous about the medical details. The film shows well the modern treatment of paraplegics, refers openly to their bladder and bowel troubles, and gives an energetic picture of reablement, in the magnificently appointed gymnasium and swimming-bath. Extra power in the arms and torso is an essential preliminary to life in a wheel-chair, and these young men set about the job seriously—too seriously, the boys at Stoke Mandeville would say. The only time they looked really cheerful over it was in the swimming-bath, where they sailed round with their seats wedged into rubber-rings, the rest of the time—lifting larger and larger dumb bells till they reached the sort usually reserved for strong-man acts—they were as solemn as prep school boys in training for the sports. In contrast, the backchat in the wards had the genuine flavour of cheerful cynicism.

All in all, the film deserves high marks on the technical aspect, but it broke down lamentably at the love interest level. The American girl, it would have us

believe, gazes at her paraplegic boy-friend with a look of steadfast sorrow, pursues him with guilt-provoking fidelity, and waits for the wedding night to tell him it is all going to be too much for her, while mamma, though she has had a year or two to get used to the prospect, makes her boy's first visit home a misery by crying audibly in the next room every night. As a rule the paraplegic's fiancée and family have so little hope at the start that they hail every sign of their man's growing independence as marvellous, and when he leaves hospital able to live an almost ordinary life they are as proud as if he were a winner in the Olympic Games. But in any case a paraplegic who is out to pull his weight is not a liability but an asset in the home, like the head of any other family.

I regret to say that I have been up before the Bench on an alleged technical offence, though fortunately for my local reputation the case was dismissed. While waiting in the yard of the court-house I had ample opportunity to study the cross section of humanity found in such places, of which I now formed a part. It was a bumper day for the court, because a gang which had plagued the county for a year or more, stealing chickens and anything else it could get, had been rounded up. It did not altogether surprise me when a man who lived next door to my home proved to be a member of this gang, and he greeted me warmly as we waited for our names to be called. What the B.C.C. would term the "quiches" were disposed of first, and I emerged a free man. During the afternoon rumours began to circulate about the fate of the gang and the sentences its members were receiving, and I wondered how many months would elapse before my neighbour was again working in his garden. I need not have worried, for late in the evening, when I was taking a walk, my neighbour hailed me, only slightly subdued, from his gateway. "That was a bad do today, doctor," he remarked, "they caught me for fifty quid." How should one reply on such an occasion? To sympathise would be to condone the offence, to say he was lucky not to be in the county gaol would hardly be tactful. I could only agree lamely that it *had* been something of a do, from all accounts, whereupon, fortunately, he launched into full details and was satisfied with my yeses and noes.

The other morning I stumbled over an up-turned potty as I hurried through the front door, late, as usual, for work. It struck me at the time as a little unusual, but being, like most registrars with family responsibilities, distracted by the cares of this life, I gave it no further thought until the same thing happened on the second and again on the third mornings. By then I thought I must take the only likely offender—to wit, my son (aged just four)—severely to task. Guarded questioning brought only the soft answer and a smooth turning of the conversation to the type of train now to be seen across the field, and a firmer approach resulted in sulkiness, tears, and, no doubt, feelings of guilt. I became worried. Was this, I asked myself, the Ego or the Id? What ghastly and be-it-ever-so-slightly deep-seated complexes were at the root of this highly abnormal behaviour? Field observation, I told myself, was the first step, and next day I was up early to gather more information. What I had failed to observe was that he is 6 inches too short to reach the Yale lock on the inner door, but the potty made all the difference. "Aren't I a good boy to bring in the *Times*?" he observed.

In my country (*not* England now) the anaesthetists are taking the lead in the surgical departments. When our chief anaesthetist told a younger colleague the other day, "I have four surgeons working for me," he wasn't far wrong. Their apparatus is getting so big and complicated that it takes two or three anaesthetists to work one machine and there is hardly room for anything else in the theatre. Their latest whim is to give every patient continuous oxygen therapy for some days after operation. I have suggested that the patients might take their oxygen masks home with them to amuse the children.

known B B C lady crooner, over heating in the E M S hut, and physical discomfort To begin with I couldn't breathe I began to realise what it must be like to have asthma, and to make matters worse I had developed a cough with tough plugs of mucus and couldn't get enough air into my chest As if that wasn't enough my intestines seemed to have thrown in their hand and to be swelling out of all recognition The night nurse had views on treatment "What about some linctus," she said, "and a little mag sulph?" "I don't mind the linctus," I replied, "but I draw the line at mag sulph It isn't that my guts won't work they can't, and it's no use being unkind to them" By the next night I was as tight as a drum but as pig headed as ever

The third day was the worst It is true the shortness of breath was better, but my abdomen was sticking up out of its window in a most sinister way I regarded it tenderly as a motorist would an inner tube beginning to bulge out of a worn cover, with no spare wheel and a mile to go home When the night nurse came on duty I surrendered unconditionally What use are theories in treatment? I spent a disturbed night, but next morning awoke completely deflated and for the first time in four days was able to face a meal

A visitor the day before had said I looked "ghastly" Now things were different I had only to lie in bed and enjoy being incapacitated I settled back comfortably to make the most of it But not for long A young physiotherapist came into the ward and proceeded to put its occupants through their paces I tried to avoid her eye, but it was no use "Ha," she said "I see you're better Time you began your exercises You can come to the physiotherapy hut at 2.30" And I went She was quite right, if I was to regain my muscular efficiency I'd got to work for it

At the end of the week I went home Trying to lead a normal life in a plaster case presented all sorts of unexpected difficulties At first quite slight exertion brought back the difficulty of breathing almost as badly as before, and even concentrating on abdominal respiration did not help, but this trouble lasted no more than a month The other disabilities were there as long as I was in the thing If I sat down, my thighs pressed on the lower edge and levered the whole jacket up, so that if I didn't keep my head vertical the upper projection jabbed me in the Adam's apple Reading and writing became difficult and so did eating, while drinking soup from a spoon was almost impossible Do you realise how many times a day you go through the motions of picking something up from the floor? I never did till I found I couldn't do it But I evolved a special technique of locating the object, putting the outside of my heel against it, doing a double knees bend, and then feeling straight down with my fingers Of course I couldn't bathe, but that was one of the lesser evils What was worse was the difficulty of drying when I had got really hot inside my shell In the end I found the solution in an electric hair-dryer I would retract myself as far as possible within my case, blow hot air around till I was dry, and then finish off with a delightful draught of cold

All this time I was keeping my muscles in trim by doing regular exercises at home, and three days a week in the hospital using the special apparatus there Some of these exercises, such as lying across a bed with my heels held, bending down till my head touched the floor, and then coming up to the horizontal again, looked much more difficult than they really were The only one I found at all exacting was walking along a 2 in bar of wood raised a foot off the floor, I felt as if I was balancing on the parapet of a house But what was most difficult of all was sustaining my interest in the ritual Perhaps this is not so bad where there are a lot of people with the same disability so that the competitive element creeps

in, but when you are alone there is often a strong inclination not to bother with it for once—and if I didn't bother once I knew I should be lost I was determined to get better, and I was prompted by fear of what might happen if I didn't "A good many people find it worse coming out of plaster than going in," the experts told me, "and it's because their muscles aren't equal to it" So I flogged away at the exercises and invented others of my own As I sat at my desk, I developed the power of contracting my trunk muscle individually, feeling them press against the plaster as they came into action In my imagination my umbilicus was a movable object, and I made it go round and round, first clockwise and then anticlockwise, like the tip of a minute hand

By the end of the twelfth week either I was getting thinner or the plaster was stretching, anyway I was beginning to rattle about inside it like a nut in its shell About the same time, too, I became aware of a constant gnawing pain through the middle of my right chest that made me want to free myself and have a good stretch At last, at the end of another fortnight, the great day came and the plaster was cut off I half expected to collapse like a jelly on the floor, but nothing of the sort happened On the contrary, I never felt so firm and fit for action in my life The other unexpected thing was that the pain in my chest grew worse for two or three days, after which it gradually disappeared Today, nearly three years after the accident, I have a wedge shaped vertebra, perfect function, and complete freedom from any unpleasant sequel

Public Health

Poliomyelitis

In England and Wales notifications of poliomyelitis during the week ended Nov 25 were paralytic 111 (111), non-paralytic 19 (39), total 130 (150) The figures for the previous week, compared with which there was a total decrease of 20, are in parentheses Uncorrected notifications for the corresponding weeks in 1947 and 1949 totalled 145 and 193

Total uncorrected notifications for 1950 to and including the week under review are 8251 The corresponding figures for 1947, 1948, 1949, are 8821, 2212, and 6327

Smallpox not Confirmed

A coloured student resident in a hostel in Chelsea, London, was removed to Long Reach Smallpox Hospital via the Brook Hospital, Greenwich, on Nov 28 Laboratory investigations and further clinical developments have now removed all suspicion of smallpox.

*Not including late returns

the local pool for remuneration of general practitioners in addition to creating ill feeling between different groups of the profession, particularly where the ex registrars appointed as clinical assistants would be seeing their colleagues' cases referred to hospital

The flooding of the general practitioner market with 1100 redundant registrars will, of course, be most convenient for the Ministry, which is at present engaged in opposing general practitioner claims for an increase in the central fund for payment of capitation fees. No proposal has been put forward for increasing this fund from the money saved by dismissing these 1100 registrars.

The suggestion (in paragraph 12 of the circular) that boards should send a polite letter to dismissed registrars was regarded as merely adding insult to injury.

The desirability of the necessary cuts in registrar establishments taking place gradually was realised, and it was pointed out that the extension of senior registrar posts for a fourth, fifth, or even a sixth and subsequent years would not only alleviate individual hardship but would reduce the annual recruitment and retirement of registrars and so allow the temporary maintenance of establishments above the proposed level without further perpetuating the disproportion between registrar and consultant vacancies. As an example, the 28 senior registrars calculated as indicated for the Welsh region on the basis of 3 year tenure could be 36 or 37 on a 4 year average tenure, and this increase would particularly benefit the non teaching hospitals, whose work and patients will undoubtedly suffer if the proposed radical cut is introduced.

G. R. VENNING
Acting Secretary
Welsh Regional Registrars' Group

Cardiff

SIR,—There is a strong argument for reducing the number of trainee specialists while there are few consultant posts falling vacant each year. On the other hand, the Ministry of Health encouraged numbers of us to take up specialist training with the promise of an increase in the number of consultant posts under the National Health Service, and it was recently reiterated in Parliament that the country was far short of the numbers required. That these posts will not be created for some time has been apparent for the past year at least, yet without prior consultation with any representative medical body, the Ministry have swung the axe.

Laments by the small number of registrars are less likely to be heard than those by general practitioners or consultants, and we are looking to these groups for support, if only against the methods used, which might later be applied to any other branch of the profession.

ANOTHER REGISTRAR

SIR,—The answer to the problem of the registrars is simple and widely agreed upon amongst the profession. The number of consultant posts must be rapidly increased to the figure which the Minister has previously held to be necessary. Registrars must take action to ensure that (1) the memorandum shall be frozen until discussions with the profession have taken place, and (2) the Minister explains why he is unwilling to solve the problem by making more consultant posts. Is it because of economic or political considerations? Or is it, as some would believe, due to the resistance of the present consultants?

If the Minister can give a valid reason for his attitude, then registrars must coöperate with him in solving the problems that will face them. But surely they must know this reason first. And until then they should not discuss with him the alternative methods of solving the difficulty.

Middlesex Hospital London, W 1

CECIL McIVER

SIR,—May I suggest that one solution to the registrar problem is the reintroduction in surgery and medicine and an increase in other specialties, of the S.H.M.O. grade?

I know that this grade has been violently opposed in the past, but then we looked forward to an expansion in the consultant services and presumed there would be an increasing number of openings for the top grade of registrar. This suggestion, or that of "Senior Registrar" (Nov 18) that senior registrars should be retained for 6 years, would seem to me to have the merit of least disrupting the hospital services. It would be disappointing to many but would not give the sense of despair that the present cut has produced.

I am completely in favour of the G.P. being more in the hospital "swim," but cannot see part time clinical assistants with conflicting calls on their time offering the service given by the present registrars.

REGISTRAR

SIR,—We registrars, suggest immediate collective action of registrars for the amendment of the Ministry of Health edict, if only to avert our financial ruin, irrespective of the wider questions of increasing the number of consultant posts and maintaining adequate hospital staffs.

We suggest two basic demands to achieve this: (1) security of tenure of non teaching hospital appointments above that as senior houseman, such as existed in the municipal hospital services, and (2) constructive proposals for those leaving the hospital service, to replace the impracticable suggestions about the Armed Forces and the Colonies contained in paragraph 12 of the Ministry's circular.

Such security of tenure will mean

(a) That non teaching hospitals will not be robbed of a vital segment of their medical staffs, a cut is bound to be at their expense as it appears unlikely that registrar appointments in teaching hospitals will be cut by half.

(b) That individuals not advancing to consultant status will drop out (as, indeed they always did) at their own convenience, and consultants will be produced by competition, experience, and qualifications instead of by any rigid and uniform time table system. Recurring artificial crises of superfluous registrars would not then arise. At present the situation can be compared to a factory where the foremen not reaching the board of directors in two years, are automatically thrown out of the industry.

The constructive proposals for those leaving the hospital service might include facilitated entry into general practice, training courses without loss of pay—preference for practices where part time work in the specialty would be available, and no sudden termination of contracts now.

We urge the most vigorous action of all registrars by personal interviews with M.P.s, through their own groups of the B.M.A., and, if possible, by a deputation to the Minister of Health.

FIELD WORK FOR STUDENTS

SIR,—In your leading article last week, you mention some of the measures taken to bring medical students into contact with general practice. Students from Guy's Hospital have been visiting the homes of patients attending the general practice of the Bermondsey Medical Mission as part of their course in social medicine. The staff of the mission have found that students and patients alike enjoy these visits. My own experience in taking part in this experiment has convinced me that much benefit could result to both parties by an extension of this method.

Letters to the Editor

REGISTRARS

SIR,—Both the action of the Minister and the reaction which it has evoked appear to me to show a singular lack of realism and a lamentable failure to grasp fundamentals. The attempt is being made to staff the hospitals by adapting a system outmoded by the rationalisation and the phenomenal advance of medicine. Such an attempt is doomed to failure. You cannot put new wine into old bottles. Moreover, there is no surer way of getting into a muddle than by calling persons and things by their wrong names. "Consultant" originally meant one who gives a second opinion. Later it became a courtesy title for those who had retired from active hospital staffs. Now it is applied to nearly all who hold part time or full time permanent hospital appointments. Anaesthetists, for instance, have become "consultant anaesthetists," a term which does not make sense. The modern registrar performs few, if any, registry functions, these having been assumed by the records officer, he is in reality a physician, surgeon, or specialist.

Before the war those who undertook the long and arduous climb to consultant rank did so with their eyes open. A great many gave it up at various stages, slipping quietly and with a good grace into general practice where their experience usually enabled them to build up a specialist practice on a less ambitious scale than they had originally hoped. The supply of aspirants was thus automatically adjusted, if not to national needs, at least to the amount of money which the community was prepared to pay. In other words, the number, and therefore the standard, was limited by the amount which could be earned in private practice. Although this factor has ceased to operate, the recollection of it persists, and inhibits clear thinking. Despite the budding off of new specialties such as pediatrics and thoracic surgery, the amount of general medical and surgical hospital work has enormously increased. Yet the number of general physicians and surgeons has not been increased, the burden of the extra work devolving upon the registrars.

In contrast to the registrars the consultants find themselves in clover. Formerly, as everyone knows, the young consultant faced a hard struggle for many years, eking out a livelihood by odd teaching jobs and depriving himself of holidays for fear of missing a patient. Now, from the word "go" he is completely relieved of financial anxiety. He has a permanent appointment at a substantial salary and unaffected by competition, six weeks' holiday with pay, sick leave and study leave on generous terms, and a pension at the end of it. He enjoys, too, the exceptional privilege of deciding for himself how much time he gives to the service.

Such wide disparity in pay and security is justified only if the consultants confine themselves to the difficult work, leaving the easier to the registrars. But this is just what does not happen. Registrars, though responsible to their chiefs and relying upon them for guidance in difficulty, carry out much of their work independently. In the absence of their chiefs on holiday they are in sole charge, at night and at weekends they perform operations which are quite as difficult as those performed by their chiefs during normal hours.

It is widely believed, both inside and outside the profession, that the whole of consultant work (using this term in its modern sense) requires unusual ability and an experience acquired only after many years of apprenticeship, and we are told that the requisite standard cannot be maintained unless there is always a large field from which to select. It is about time this bubble was pricked. Great experience and judgment certainly are required, but, under modern hospital conditions,

only in a minority of cases. With all due respect I cannot see that these qualities are required in order to refer a patient for X ray examination at the request of his doctor, a second to the dietitian for weight reduction, or a third to the physiotherapist for the treatment of so called fibrositis of the neck. Still less can I see that they are required for the strange new practice of writing to the doctor a lengthy and quite gratuitous account of the patient's symptoms—facts with which the doctor is perfectly familiar and which form the reason for his sending the patient. Yet this kind of work looms large in outpatient departments and is performed by consultants and registrars indiscriminately (incidentally keeping thousands of typists happily employed). Can it be seriously maintained that it calls for exceptional gifts or involves heavy responsibility?

Since the wholesale reference of patients to hospital is deemed necessary to a science worshipping society, somebody has to do the work. The consultants could not cope with it even if they gave up private practice, which few of them would be prepared to do. They have come to rely on the registrars for the performance of work which is nominally theirs. Moreover it is owing to the provision of registrars that they have been enabled to continue private practice. They therefore cannot stand by and watch those who have served them so well thrown to the wolves. They cannot profit from an outrageous system whereby the State entices people into its service and keeps them on probation until the age of about 35 (half man's allotted span). Moreover, the State may well be compelled by circumstances to decree that private consultant practice is incompatible with employment in the service.

The solution therefore is perfectly clear. Permanent establishments should be increased until they are sufficient, and there should be a much closer approximation of pay, even if this means, as it inevitably must, a reduction in the salaries of existing consultants. In view of the heavy incidence of surtax, those who enjoy distinction awards will at least be consoled by the knowledge that they are handing their money over to their fellows instead of to the Chancellor of the Exchequer. Meaningless designations and obsolete concepts of status and dignity must be abandoned and, within the limits set by the national finances, work must be rewarded on the only rational basis—namely, the intellect and craftsmanship needed for its performance.

Cambridge

FFRANGCON ROBERTS

SIR,—I have been instructed to report the resolutions of the Welsh Regional Registrars' Group at a meeting held in Cardiff on Nov 25. The resolutions were passed unanimously by the 32 members present, amongst whom were representatives of most parts of the region.

While the Ministry's circular¹ was condemned as being a totally unsatisfactory solution of the registrar problem, certain features were singled out as being particularly unacceptable.

The instruction in paragraph 9 (u) that registrar and senior registrar appointments be reviewed annually and where necessary terminated on the implementation of the reduced establishments, was regarded as representing flagrant breach of contract where appointment has already been made for 2 or 3 years in accordance with the terms and conditions of service.

The recommendations in paragraph 11 (b) that general practitioners "with registrar experience" be appointed as part-time clinical assistants were unanimously condemned as completely unacceptable.

The appointment of ex-registrars as part-time clinical assistants while engaging in general practice near their hospital work would be as unacceptable to the previously established general practitioners in the area as to the displaced registrars. It would lead to further attenuation of

¹ See *Lancet* Nov 11 1950 p 537

sugar level remained low, showing that the tuberculous meningitis was still in an active stage.⁶

It was more difficult to interpret the cases—seen mainly before sufficient experience was gained with streptomycin therapy—where the cell and protein content were more or less increased and the sugar content was normal but potassium permanganate reduction was produced within five minutes.⁷ In my opinion, these cases are in the active stage. Here increased sugar content does not indicate healing, and it may be brought about in several ways, such as by the encephalitis, extensive tuberculomata in the brain, tuberculous abscesses, oedema cerebri, disturbance of regulation by the diencephalon, or disturbance of reabsorption of C.S.F. The strength of these enhancing factors outweighs the lowering influence of meningitis.⁸

There are two other interesting groups. In one tuberculous leptomeningitis is cured and the C.S.F. is normal, but cerebral tuberculosis is in an active stage. Arcyn and Ivanovszkaja⁹ have found this condition in 6% of cases examined post mortem. Tubercle bacilli could easily break into the C.S.F. from the cerebral foci. On the other hand, the patient can be cured clinically, as well as by the criteria of C.S.F. cell, protein, and sugar content, and yet tubercle bacilli can be detected in the fluid. In Levinson's¹⁰ opinion, in such cases no further streptomycin treatment is necessary.

Volcsok et al.¹¹ suggest that when tubercle bacilli are found in the C.S.F. of patients who have been treated with streptomycin for tuberculous meningitis, this treatment should be immediately recommenced even if the C.S.F. is entirely normal.

Brody Children's Hospital, Budapest

BELA STEINER

POTENTIATION OF SULPHONAMIDES

SIR,—I have read with interest the article by Professor Bigger and Mr Ware, and also the annotation, in your issue of Sept 30, and I agree completely with your remarks. It would be a pity if the widespread practical application of a potentiated form of the first broad-spectrum chemotherapeutic to have been evolved were hampered either by the untimely retirement of Professor Bigger or by the undivided attention now being given to the fermentatively produced antibiotics.

Goldberger,¹² who is attending surgeon to this hospital, was apparently able to convert the "bacteriostatic activity" (to use Professor Bigger's term) of various sulphonamides to bacteriocidal effects, by the use of defined chemically pure substance the prototype of which was azochloramide. Further investigation by Goldberger and his associates indicated that most oxidising agents, whether or not they yielded molecular oxygen (we should now term them "deelectronators"), potentiate sulphonamide derivatives. In the past four years this chemical laboratory discovery has been applied here in the management of wounds and wound infections, with what appear to me excellent results. By others perhaps the significance of these findings may not have been fully recognised, owing to the present day reliance on fermentatively produced antibiotics (though in many respects these may be decidedly inferior for direct application to wounds).

From Dr Goldberger's original study it is possible to infer a degree of ubiquity for the thermostable potentiator described by Dr Bigger and Mr Ware. This may prove to be a ferric porphyrin derived from cytochrome

oxidases present in many biological materials, for though an enzymatic oxidase would be as vulnerable to heat as any protein the "haem" prosthetic nucleus is relatively indestructible, and under appropriate conditions of pH and redox potential may be as effective an deelectronator as the oxidising agents in the category first used for sulphonamide potentiation by Dr Goldberger.

ROBERT D BARNARD
Clinical Hematologist

CHEST PHYSICIANS AND TUBERCULOSIS

SIR,—There is a widespread tendency amongst chest physicians either to ignore some of the basic facts of tuberculosis, or else to refuse to face them. Perhaps it is because a modern chest physician is so occupied with therapy that he has little or no time for prophylaxis. This is a most serious matter in pulmonary tuberculosis, where prevention is much more important than cure.

The preventive efforts of chest physicians are limited today to a few large film or screening sessions, and periodic exhortations to general practitioners to forward cases that might have suspicious symptoms. It is true that some chest physicians with fluoroscopes do some times find active disease, but as a preventive measure their methods are as hopeful as trying to empty the Serpentine with a pint pot. Indeed one might say that the preventive measures of chest physicians are like a man pouring water into a bucket, not with a hole in the bottom, but with no bottom at all.

The present tuberculosis service is a superstructure built on an insecure foundation—insecure because it is mainly ignorant of, and impotent to deal with, the large underground reservoir of infection. Unless this reservoir is drained there is, despite declining mortality, no hope for any major advance in the control of tuberculosis in the next five years. If this is doubted, appraisal of the facts might help. For instance, in a London population of 300,000 people, served by a well organised chest clinic, at the present moment the number of undiagnosed active cases requiring treatment is more than twice the number of active cases seen by the chest physician in the whole year. At present we allow the stream to flow from the reservoir, and in time to grow into a veritable river.

It is high time that much greater attention was paid to the prophylaxis of pulmonary tuberculosis. The present practice of relying on symptoms for case-finding is inadequate, and it is to well organised half yearly routine radiography, on 35 mm film, of all susceptible age groups that we must look for help. The disadvantages of such a scheme are great, but not great enough to put it out of court. The advantages are so evident that it is unnecessary to list them.

No doubt I shall be severely taken to task for suggesting methods that would swamp the already insufficient tuberculosis beds, but, as Dr Toussaint has shown in Willesden, there is great scope for the domiciliary management of tuberculosis. Much of the disease discovered by routine radiography could be treated by this means.

Laennec wrote in 1819, seven years before his death from pulmonary tuberculosis: "Small tubercles separated from one another by portions of healthy lung cannot be recognised. But at this period of their progress the health is commonly still good and the cough too slight to induce the patient to consult a medical man." Here Laennec clearly stated the whole problem of early diagnosis and the case for routine radiography. Laennec had to rely on symptoms and the stethoscope for his case finding. We do not. We have radiography and the laboratory. But whereas Laennec was able fully to exploit the stethoscope in his short life time, we have not yet so used routine radiography. Today there are many chest physicians who make pleas for the early diagnosis

SALICYLATE AS AN ANTICOAGULANT

SIR,—I was interested to see that at a recent meeting of the British Cardiac Society Dr J L Lovibond, who had investigated the value of salicylate in the treatment of coronary thrombosis, reported that this drug is an unpleasant but safe anticoagulant for domiciliary use. He found that few patients were able to tolerate sodium salicylate or calcium aspirin ('Disprin') in the massive daily dosage of 200 grains for many days. This is not surprising, for sodium salicylate is notoriously more prone to induce toxic symptoms than aspirin and has the serious disadvantage of increasing the sodium content of the body, and calcium aspirin has nothing to recommend it in the treatment of thrombosis, as a substitute for aspirin, except its solubility.

I am still using aspirin in suspension as a routine treatment for phlebitis, pulmonary embolism, and coronary thrombosis, in doses of 20 grains four hourly—i.e., 160 grains daily. When the instruction to give the mixture with milk or other food is strictly adhered to, the patient seldom complains of any discomfort referable to the drug. There is a big difference between giving 20 grains of aspirin powder on an empty stomach and 20 grains in suspension with food, but it is surprising how many apparently intelligent people do not appreciate this. It would be a great pity if a safe and simple remedy of proven value in the treatment of thrombotic diseases were to be discarded for the lack of a little common sense.

Torquay

PAUL GIBSON

MYXŒDEMA FROM RESORCINOL OINTMENT APPLIED TO LEG ULCERS

SIR,—In their article of May 6, Dr Bull and Dr Fraser reported myxœdema in three elderly women who had for a long time received applications of resorcinol ointment for varicose ulcers. In each case sections of the thyroid gland showed signs of hyperactivity characteristic of the action of an antithyroid drug. In the same issue Dr Domach and Dr Fraser confirmed the antithyroid activity of resorcinol in animals and found that thiouracil does not enhance this activity.

We therefore thought it desirable to study the histological response of the thyroid in animals after administration of resorcinol.

For this purpose seven rabbits (six bucks and one doe) were used, and five bucks served as controls. All of them belonged to pure strains (Moravia Black, Silverblack, Chin chinella), were 5–8 months old, and weighed 1220–2300 g. They were kept in the usual wire cages and were fed on hay, bread, and oats.

Resorcinol was administered subcutaneously as a 1% solution in 0.9% saline solution, 50 mg per kg body weight was given for 4 days and 75 mg for 15 days. The total amount of resorcinol administered was therefore 1325 mg per kg. The absolute amount administered during the 3 weeks of the experiment varied from 1598 mg to 3096 mg according to the weight of the animal. The drug was tolerated fairly well by the end of the experiment the animals had lost about 5% of their weight. They were then killed by air embolism. The thyroids of these animals showed no signs of enlargement (their weight averaged 95 mg), nor any change in their tender consistence or in their colour compared with those of the controls. Likewise the histological picture did not differ from that in the control animals apart from changes that were within normal limits.

To observe the effect of methyl thiouracil and resorcinol administered together, the former was given subcutaneously to seven rabbits in doses of 100 mg per kg body weight in N/10 solution of sodium hydroxide six times weekly for 9 weeks (total amount 9040–11,105 mg). From the 7th week four of the seven animals received resorcinol subcutaneously as in the previous experiment. All seven rabbits were bucks, of pure strain, kept under the same conditions and killed in the same way as in the previous series. The thyroids of all seven animals were greatly enlarged, their weight averaged 735 mg and they had a fleshy red colour and firmer consistence. Histological examination revealed in each case

the well known effect of methyl thiouracil, and this effect was in no way modified by the resorcinol.

Thus the administration of resorcinol does not change the histological structure of the thyroid in rabbits, nor does it influence the effect of methyl thiouracil administered simultaneously.

SIMPLE TEST FOR PREGNANCY

SIR,—For the past ten years I have been using a simple clinical test for pregnancy.

It consists in injecting 5 mg progesterone on three alternate days. The absence of withdrawal bleeding is a positive sign of pregnancy. If the amenorrhœa is due to any other cause, bleeding occurs in about 5 days. Cases of obstruction—congenital or acquired—and of absence of the uterus can be easily excluded by bimanual examination. I have had no chance to use the test in cases of hydatidiform mole, but I expect that it would be positive.

Suhag Upper Egypt

M EL MISHAD

TUBERCLE BACILLI IN THE CSF

SIR,—In your annotation of Aug 19 you remark that "many factors concerned in the pathogenesis of tuberculous meningitis are still imperfectly understood."

We have learnt that tubercle bacilli may be found in the cerebrospinal fluid (CSF) without clinical or pathological evidence of meningitis. We do not know why the presence of tubercle bacilli in the CSF is not always followed by tuberculous meningitis, or why in some cases the meningitis is only circumscribed. Rich¹ suggested that very numerous bacilli are necessary to produce meningitis. Schwarz² has often seen cases where caseous masses have broken down into the subarachnoid space without a violent reaction, even in the presence of numerous acid fast bacilli. It seems that the number of tubercle bacilli is not the deciding factor in every case. Koch³ suggested that tubercle bacilli can multiply in the CSF. It might be reasonable even to assume that phagocytosis may take place when the organism gets into the CSF, and the effectiveness of this could decide whether or not tuberculous meningitis will develop.

During treatment of military tuberculosis with streptomycin tubercle bacilli may be found in the CSF while tuberculous meningitis is developing, without any clinical evidence. For this reason diagnostic lumbar puncture should be performed periodically on patients with military tuberculosis. In diagnosis CSF sugar estimation can help in distinguishing tuberculous meningitis from a tuberculoma in the meninges or the brain. With each the protein level and the number of the cells is increased, but whereas in tuberculous meningitis the cells usually exceed 20 per c mm—usually they number 50–300 though they may exceed 1000—with tuberculoma the number remains under 20 per c mm. In tuberculous meningitis the sugar content is low and continues to fall,⁴ whereas in tuberculoma the sugar content is normal. Tuberculoma may or may not produce meningitis, so it is perhaps best to avoid the diagnosis of "serous tuberculous meningitis," suggested by Lincoln,⁵ because this might give the patient or parents a false sense of security. It is no surprise that we can detect tubercle bacilli in the CSF of patients with tuberculous meningitis who have received intrathecal streptomycin and have been regarded as clinically cured. I have often found that when a child seemed to be "clinically cured," the cell and protein content of the CSF decreased while the

SIR,—We have followed with interest the controversy over the effect of deoxycortone and ascorbic acid in rheumatoid arthritis since the original communication of Lewin and Wassén. Rheumatoid arthritis is a disease notorious for its exacerbations and remissions, so that any evaluation of the efficacy of a given therapeutic regimen in this disease is admittedly difficult. The dramatic and definite clinical response to 'Cortisone' and ACTH in all or almost all cases of rheumatoid arthritis, however, cannot be questioned.

It occurred to us that the comparison of the response of the same patient to Lewin and Wassén's regimen and to cortisone would be a more objective method of evaluating this method of therapy. We have therefore given 4 patients with classical severe rheumatoid arthritis a two week course of cortisone. Therapy was then discontinued for two weeks, after which they were given a two week course on the exact regimen outlined by Lewin and Wassén, with injections once daily. All 4 patients had a rather dramatic response to cortisone, with alleviation of their arthritis. After two weeks off therapy, 3 of the patients had relapsed while 1 remained in remission. The relapse continued and indeed increased in severity during the next two weeks in these 3 patients, despite daily injections of deoxycortone and ascorbic acid. The fourth patient has remained in remission to the time of writing, six weeks later.

In this study deoxycortone and ascorbic acid had no noticeable effect on the clinical manifestations of rheumatoid arthritis. Our results are strikingly similar to those of Dr Dresner and his colleagues¹.

U.S. Marine Hospital
Baltimore,
Maryland U.S.A.

LUTHER L. TERRY
FRANK LONDON

SIR—Cranswick and Hall,² who treated 37 mental patients with deoxycortone and ascorbic acid, noted temporary benefit in 11 depressives with a history of less than one year, and in 4 of these the depression remitted. Moreover, of 12 patients who benefited previously or subsequently from electroconvulsive therapy (E.C.T.), 11 also showed a positive reaction with deoxycortone. Bourne³ reported complete failure to confirm these claims and found no favourable response in 9 patients, 8 of whom later did well with E.C.T.

Although the claims made for this treatment in its original field of application—rheumatoid arthritis—had also been refuted,⁴ we thought it desirable to run a preliminary therapeutic trial, in which 30 patients, suffering from a depressive illness (excluding patients with schizophrenia or cerebral disease) were treated with deoxycortone and ascorbic acid.

The group consisted of 12 male and 18 female voluntary patients mainly over the age of 40 (average age 50.3 years, with 8 patients over 70 and only 3 under 30). 11 patients were severely depressed, in 10 the depression was only moderate, and in 9 the affective disorder was mild though still justifying the use of E.C.T. as a last resort.

Most of the patients were treated in accordance with an agreed programme which provided for six intramuscular injections of deoxycortone acetate in oily solution followed immediately by intravenous injection of 1 g. ascorbic acid, given every other day. The technique was that of Lewin and Wassén,⁵ which had been employed by Cranswick and Hall, and the sequence of dosage was 2.5 mg., 2.5 mg., 5.0 mg., 5.0 mg., 2.5 mg., 2.5 mg., any dose followed by clinical improvement was to be repeated at lengthening intervals. Supplementing clinical observation, numerical ratings of the mental state were recorded before, during and after the treatment on a modified version of the Worcester behaviour chart.

In no case did we obtain convincing evidence of changes comparable with responses to E.C.T. In 4 cases improve-

ment followed the course of deoxycortone, however, 2 cases soon relapsed and failed to respond to further injections, but remitted satisfactorily with E.C.T. Short spells of subjective well being and cheerful overactivity occurred in 8 patients two to three hours after an injection and lasted a few hours, but these results were not consistently repeated. The most marked reaction occurred in a mildly depressed man, aged 53, who had never shown any manic components to his illness, but who after his fourth injection (5 mg.) became elated and flirtatious, with a voracious appetite, for a few hours followed by more profound depression on the following day, later E.C.T. produced only temporary benefit. 22 patients were given E.C.T., generally one week after the deoxycortone course and in 18 the depressive symptoms responded satisfactorily. Of the 30 who received deoxycortone between June and August of this year, 21 have so far been discharged.

While occasional euphoric episodes following some injections of deoxycortone are of interest and may deserve further investigation, our results have convinced us that deoxycortone and ascorbic acid is unlikely to find a place in the treatment of depressive illness.

Bethlem Royal Hospital and
Maudsley Hospital

D. L. DAVIES
A. HARRIS
F. POST

SIR,—Among the diseases which may occur in his general adaptation syndrome Selye¹ includes several skin conditions, such as lupus erythematosus, scleroderma, and psoriasis, and in the few cases in which A.C.T.H. has been tried in the United States the response of these ailments seemed encouraging.² Conflicting reports have followed the publication by Lewin and Wassén³ of their successful results in rheumatoid arthritis treated with deoxycortone and ascorbic acid, but nevertheless it was decided to try this combination in cases of these skin diseases. Some cases of alopecia areata have been included on the grounds that this disease also is the result of a failure in the normal response to stress.

The patients were treated for 6–8 weeks by one of two routines: (1) deoxycortone acetate 5 mg. intramuscularly and ascorbic acid 1 g. intravenously once a week, or (2) deoxycortone 5 mg. and ascorbic acid 0.5 g. injected by the same routes as in (1) twice a week. There was no significant difference in the results of the two methods, and whichever routine was the more convenient was chosen for the individual case since all but one were treated as outpatients. Erythrocyte sedimentation rates (E.S.R.) were estimated at the start of treatment and at regular intervals subsequently.

RESULTS

Lupus erythematosus—Of the 10 cases treated, 1 was slightly improved but subsequently relapsed, 2 became worse, and the remaining 7 were unchanged. These results were confirmed by the E.S.R. readings where the E.S.R. was initially raised it remained raised with minor fluctuations, and where it was originally within normal limits it remained so.

Psoriasis—Of the 8 cases 3 were given as controls, 5 ml. of physiological saline solution intravenously twice a week for four weeks. Of the 5 treated with deoxycortone acetate 2 were improved and will probably clear completely, 2 showed no change, and 1 was worse. Of the controls, 2 were improved and will probably clear completely. In 1 case treated with deoxycortone, where there was associated rheumatoid arthritis, the psoriasis was greatly improved but the arthritis was unchanged, as judged by the clinical appearances, measurement of the wrist-joints, and the E.S.R., this was the only case of psoriasis in which the E.S.R. was raised.

Scleroderma—3 cases were treated without benefit, though 1 showed initial subjective improvement.

Alopecia areata—Of 7 cases treated 2 long standing ones improved, and the remaining 5 showed no change. All these cases have been observed for three months from the start of treatment. The E.S.R. was normal in every case.

DEOXYCORTONE AND ASCORBIC ACID

SIR.—Lewin and Wassén¹ recently reported the treatment of rheumatoid arthritis with deoxycortone and ascorbic acid. Thereafter, some early reports² were hopeful, but latterly the effect has been recorded as slight or nil.³

At this hospital 20 cases of rheumatoid arthritis, affecting the peripheral joints, have received this treatment. In several cases the arthritis was associated with other lesions: in one recurrent inoperable carcinoma of the bladder, in another severe secondary amyloidosis with renal and hepatic involvement, in 3 mild essential hypertension, in 2 generalised scleroderma (in one of these luetic aortitis with hypertension was also present), and in another chronic asymptomatic lymphatic leukaemia.

All patients received a daily intramuscular injection of 5 mg of deoxycortone ('Percorten' in oil), followed within five minutes by 1 g of ascorbic acid (aqueous solution) intravenously. Before treatment was instituted, each patient was thoroughly examined and his history was carefully elicited. Affected joints were radiographed and a complete blood count and erythrocyte sedimentation rate (Westergren method), plasma cholesterol and

I showed moderate improvement, the remainder were unaffected.

In no case did the ESR fall, nor was any change in the chemical composition of the blood detected. No patient reported the exhilarating effect recorded by Lewin and Wassén. Observations of the blood pressure in 3 patients with hypertension on admission showed that the levels fell to normal under treatment, but in one patient the pressure rose, while in another the onset of fatal pulmonary oedema may have been precipitated by the treatment.

CASE 20—This patient, a woman, aged 65, had arthritis, scleroderma, hypertension, and luetic aortitis. She received, as an inpatient, 8 days of treatment, and on the 8th day suddenly developed acute pulmonary oedema followed rapidly by death. The sudden acute heart-failure may have been precipitated by deoxycortone, which is a pressor agent.

This treatment is not a cure for rheumatoid or rheumatoid like arthritis.

Mount Sinai Hospital,
New York City

SELVAN DAVISON

SIR.—We have administered these two substances to patients with the following disorders: rheumatoid arthritis (10), osteoarthritis (3), ankylosing spondylitis (4), traumatic arthritis (2), acute sciatica (3), and acute (1) and subacute (1) rheumatic fever.

In the majority of cases 5 mg deoxycortone acetate was injected intramuscularly, and within five minutes 1 g ascorbic acid intravenously. In some cases both drugs were given intravenously, with apparently more rapid results. In 3 cases both drugs were given together intramuscularly from the same syringe, with no response at all, all 3 cases responded, however, when one of the two other methods was used. The results were as follows.

Rheumatoid Arthritis—Of the 10 cases, 8 were in a phase of acute exacerbation, with fever, loss of weight, depression, and manifest vasomotor disturbances. In this group of acute cases, within two to six hours the pain was distinctly relieved and the range of movements much increased. Improvement was maintained on the average for twelve to twenty-four hours, and was again produced by repeating the treatment. With each repetition the duration of improvement increased, so that after the fourth day the injections were given only every two to three days. After 10 treatments, 7 patients had continuing relief though some pain returned, the 8th relapsed after two days, but a second course of 10 injections has produced a remission which has persisted for two months.

The other 2 cases were not benefited, but 1 responded to a second course after small doses of thyroid and oestrogenic hormone had been given for six weeks.

Osteoarthritis—The response was uniformly unsatisfactory.

Ankylosing Spondylitis—The response was extremely satisfactory. In 1 of the 4 cases the patient's posture before treatment was similar to that in postencephalitic parkinsonism. After four hours the range of movements had greatly improved and this improvement lasted twelve hours. After the second injection the improvement continued for twenty-four hours. On cessation of treatment the 4 cases reverted to their former condition.

Traumatic Arthritis—In both cases pain and swelling were completely or almost completely dispelled, and the range of movement was increased; some improvement persisted when treatment was stopped.

Acute Sciatica—The response was on the whole satisfactory, and in some cases it was spectacular.

Acute and Subacute Rheumatic Fever—No response was noted.

Thus the method seems to be of value in rheumatoid arthritis, especially of the more acute type. In spondylitis and traumatic arthritis it may provide symptomatic relief, and relief was also noted in 2 cases of acute sciatica.

TROPHIC AND TROPIC

SIR,—In reply to Professor Dible's letter last week, I would point out that the arguments seem in favour of "trophic" rather than "tropic". Common scientific words in botany are "geotropic" and "heliotropic," which indicate a turning to the earth or a turning to the sun. The hormone from the anterior lobe of the pituitary does not turn to the thyroid gland, nor is it attracted by the thyroid gland, but it exerts a most important influence on the development of the thyroid gland. In its absence the thyroid gland diminishes to a very small size, it undergoes "atrophy", it does not undergo "atrophy". Surely it is clear that the words "thyrotrophic" and "gonadotrophic" are correct

J HAROLD BURN

REVOLT AT KINGSTON

SIR,—The letter from Dr Stark Murray in your issue of Nov 25 will I am sure, not be accepted as a strictly factual survey of the position that has arisen at Kingston.

1 It is only beginning to be appreciated what autonomy the regional hospital boards possess, and it has been widely known for some time that they do not publish their plans in advance in order that they may be considered and commented on by interested bodies generally. Recommendations of the board's committees involving considerable and fundamental changes in the hospital arrangements of a particular area are accepted by the board as its policy, and it is only thereafter that the area concerned is informed. Representations of any sort, at any level, made subsequently appear to be unavailing.

2 Who is to decide on the best use of hospital beds in any particular district? This question, I submit, is crucial in the whole problem of hospital accommodation. Should a remote body, the regional hospital board, or a local body, the hospital management committee, be the arbiter? In the present "set up" neither body seems to be really representative of the people. The members of both are nominated with the hospital management committee responsible to the regional hospital board but the latter, according to the Minister, actually responsible to no higher authority. Surely in this age of democracy a method of election by really interested parties from below upwards is not beyond the wit of man.

3 Dr Murray is quite wrong in saying that the general practitioners exercised a close control on the number of doctors using the Victoria. True, the number was increased in 1948 owing to a considerable influx of younger men after the war. Nevertheless no general practitioner who has applied for admission has ever been refused.

In 1938 the lay committee of the Victoria Hospital agreed that Dr Stark Murray should be appointed as pathologist for three years. By 1941 the emergency pathological service of the Ministry of Health was in operation. Dr Murray was in local charge of this service, which did the pathology of the Victoria. The question of his appointment was not reopened, and in consequence he has not been a member of the "elected consulting staff" since that year.

In his statement on the medical review of the region by the board, Dr Murray states he was a member of the review committee and that he also supplied evidence. In addition he is a member of the regional board and its medical advisory committee. Now, it is an established axiom of British jurisprudence that no one can at the same time be witness member of the jury and judge. But, by his own statement this is what happened. This action provides incontrovertible

evidence for our demand for an impartial public inquiry—the recommendation of which we are prepared to accept in advance.

4 The board has not offered the general practitioners 38 beds in exchange for the Victoria. It has offered a "hospital" obsolete for fifteen years, with no facilities of any sort worth talking about, and which is capable of holding at most, 24 beds for acute sick. Despite inquiry, no information whatever of what consulting staff may be available has been given. The hospital service of the area has always been mainly based on specialists. Why de grade the general practitioners from a position they have held since the founding of the hospital in 1898 to one of considerably lower status? It is through the present arrangement that the general practitioners are able to maintain a reasonably high standard in the domiciliary service they offer to the population generally. If this present arrangement is destroyed—and if Dr Murray's advice is taken it will be destroyed—then the standard of general practice will inevitably fall, the patient will be the loser, and the service will suffer. Is it the policy of the regional hospital board to build up a hospital service at the expense of the general practitioner service? If this is so, I am sure it is not what Parliament intended.

Dr Murray is quite wrong in saying that in this group there are no beds solely under general practitioners. Apart from Kingston and Richmond, all the beds are solely under the general practitioners, with of course, specialist cover available. This is one of the features we are anxious to preserve. The addition of "special unit" accommodation does not in any way depend on the change of use of the Victoria.

5 To say that the staff of the Victoria has never held a meeting to discuss the question—who on earth is going to believe such rubbish? Dr Murray has never been invited, because, as I have pointed out, he is not accepted as being a member of the staff.

Further, Sir, you will find that when the petition which is at present being circulated is presented, a large proportion of people in the boroughs of Kingston and Malden will be shown as having expressed their opinion against the proposal.

Indeed, wiser counsels must prevail. We have never refused "to sit round a table with those who have the arduous task of running the hospitals" to discuss the matter in its entirety. In fact we have never been asked to do so. We would be delighted to have the opportunity to put the case for the retention of the general practitioner hospital as an essential feature of the National Health Service. This type of inquiry is that demanded recently by the British Medical Association.

New Malden Surrey

CHEMICAL PROPERTIES OF P.A.S

SIR—In the course of a study of *p* aminosalicylic acid (P.A.S.), this substance was found to have certain chemical peculiarities which may be relevant to studies of its bacteriostatic effects.

P.A.S. is a very strong reducing substance. Potassium permanganate solution and potassium ferricyanate in the Hagedorn Jensen system are reduced far more by it than by sodium salicylate. But P.A.S. has the following chemical qualities, which sodium salicylate does not possess.

1 It binds a large amount of iodine from an iodine solution.

2 In the presence of sunshine it increases the separation of metallic silver from the complex silver aminohydroxide and if this latter is mildly warmed it selects a silver mirror from it. It greatly enhances the separation by sunshine of silver from photosensitive silver phosphate. This is important for the estimation of urinary phosphatase.

The urine of patients treated with P.A.S. reduces Nylander solution, but Fehling's solution it reduces not at all or only very slightly. We find that the reducing substance is not a sugar. We have, however, found glycuronic acid in the urine of patients treated with P.A.S.

Z HORN

S BOGSCN

Koltöl Anna Hospital Budapest

There were no dramatic results in any of the cases treated. Lupus erythematosus and scleroderma do not seem to be materially benefited by this treatment. Of the 5 treated cases of psoriasis 2 improved, but so did 2 of the 3 controls, so one cannot attribute the change to treatment. The improvement in 2 out of 7 cases of alopecia areata in the absence of any controls can also hardly be credited to the deoxycortone. All in all, we are inclined to attribute the improvement noted in 4 cases out of the series of 25 (excluding controls) to the psychological effect of the injections.

We wish to thank Dr George Harvey for permission to publish these cases.

Royal Infirmary, Glasgow

J O'D ALEXANDER
THOMAS COCHRANE

FLORENCE NIGHTINGALE

SIR,—I submit for consideration the theory that Florence Nightingale suffered from hyperthyroidism which later turned to deficiency and mild myxoedema. Her outstanding intellectual powers were fortified by the demonic energy that excess of thyroid secretion gave her, and which caused her to use ruthlessly all her friends and relations in pursuit of her objectives. It explains the prostration, heart attacks, and so on which caused her friends to believe her to be dying, and, too, the calmness and placidity of her later years.

There is no suggestion in the "Life" of a goitre, on the other hand, she would not allow herself in her active years to be photographed, and so no record is available. The photograph that is reproduced is one taken at the age of 70 and, though a profile, is very suggestive of myxoedema.

Coventry

W FRASER ANNAND

ST PAUL'S CRAY APPOINTMENTS

SIR,—It is quite evident that the four doctors whose letter appeared in your issue of Nov 25 (p 655) did not read my speech, as I have never, in the House of Commons or elsewhere, alleged "that the LCC had 'appointed'" them. What I said was

"I found that Dr J D Paulett was granted, by the county council, a house compulsorily acquired from a private owner and that having got those premises, he applied to the Medical Practices Committee, saying he had been granted, not a house, but the doctor's house on the estate and, therefore, asked them to give him permission to practise.

"At that time, there were other doctors who had submitted their names to the London County Council as wishing to practise on this estate, but only the name of Dr Paulett appears to have gone forward and, as there was only one applicant and a growing demand by a new population, the Medical Practices Committee had no option but to appoint him. Subsequently, a second doctor, Dr L M Franklin, was appointed to Dr Paulett's practice. He had been on the London County Council list for houses, but he subsequently acquired one privately in the area and withdrew his name from the county council list. Later, a third doctor, Dr Tuckman, was appointed to practise, he having applied to practise with Dr Paulett. Finally a Dr Tepper was appointed. He was allocated a London County Council house on the estate, and he applied to the Committee that he might be permitted to practise, having had premises and facilities given him by the LCC. From this it will also be seen that I made it quite clear that only two were LCC tenants.

It is, I understand, the policy for these new estates that the medical practitioner should live on, or in the immediate vicinity of, the estate. The physical possession of premises is, therefore, valuable and indeed vital to appointment, and where council houses are available, the selection of a tenant for the doctor's house, before appointment by the Medical Practices Committee, must prejudice the chances of other doctors, equally qualified and anxious to practise, but not granted a tenancy.

ROYAL MEDICAL BENEVOLENT FUND

SIR,—As Christmas day is near at hand I should like to remind your readers of our Christmas gifts fund, in the hope that those who have not sent their contributions will now do so quickly. We must not fail in bringing happiness and extra comforts to our beneficiaries. Contributions should be sent to Royal Medical Benevolent Fund, 17 Billiol House, Manor Fields, Putney, London, S W 15, marked "Christmas Gifts," and will be gratefully acknowledged.

C LUTHER BATTESON
Honorary Treasurer
Royal Medical Benevolent Fund

ORAL STREPTOMYCIN IN GASTRO-ENTERITIS

SIR,—In view of the contradictory reports regarding the value of streptomycin by mouth in gastro enteritis of infancy and early childhood, and because of the vital importance of any successful therapy, especially for this country where about half the fatalities in the first year of life are due to this cause, this treatment has been carefully studied in our hospital.

Altogether 60 infants were given streptomycin by mouth. Of these, 30 were severe cases of acute toxic dyspepsia, and the other 30 were chronic cases of severe gastro enteritis which had for months resisted all treatment, dietetic and chemotherapeutic, and many of which had passed into a marasmic state sometimes complicated, for example, by nutritional oedema or bronchopneumonia. Over 90% showed *Bact coli* on stool culture. The results are summarised in tables I and II.

In the acute series (table I) the 100% recovery rate, with only 6% relapses, suggests that streptomycin exerts a curative action. Nevertheless, a good number of these acute cases respond to ordinary conservative measures, so that small differences in percentages are not decisive.

The evidence in the chronic resistant cases (table II), however, is fairly conclusive. All these cases had for months resisted all other measures, and over 90% were cured with administration of streptomycin by mouth. Sometimes the response was dramatic. For example, in one case chronic severe diarrhoea of six months' duration was cured in thirty six hours and did not relapse in the subsequent three months, and in another chronic vomiting which had persisted for one month was cured in two days. We believe that the response in these chronic resistant cases puts the value of oral streptomycin therapy beyond doubt.

We would advise the use of streptomycin by mouth in all cases of chronic resistant gastro enteritis, especially those revealing *B coli* on stool culture, as to the acute

TABLE I—ACUTE TOXIC CASES

Treatment	No of cases	Response		Deaths	Av increase in weight per week (g)	No of cases becoming chronic	Relapses
		Within 1 week	Over 1 week

Controls (sulpha guanidine)	30	18 (60%)	6 (20%)	(13.3%)	50	(6.6%)	(20%)

TABLE II—CHRONIC CASES

Treatment	No of cases	Cases responding	Interval before response	Deaths	Relapses
Streptomycin	30	29 (97%)	1-21 days	1 (3.2%)	2 (6.6%)
Controls	30	0	—	—	—

Parliament

Voluntary Euthanasia

IN the House of Lords on Nov 28 Lord CHORLEY asked the Government at any rate to accept the principle of voluntary euthanasia so that legislation could be introduced in due course. He suggested that euthanasia might be granted on the following conditions

The sufferer must be not less than 21 years of age, of sound mind and suffering from an incurable and fatal illness involving severe pain. He must make application in writing on a form signed in the presence of two witnesses. The application must be supported by two medical certificates one from the applicant's own doctor and the other from a doctor with special qualifications for dealing with these cases, the application must be made to a referee appointed by the Minister of Health, and the referee must personally see the sufferer to ensure that the conditions had been fulfilled and that the patient fully understood the nature and purpose of the application. Euthanasia would be administered by a doctor from a special panel maintained for the purpose.

The ARCHBISHOP OF YORK opposed the proposal not through lack of sympathy but for religious and social reasons. He could not criticise the doctor who with a full sense of responsibility, alleviated pain, even if by so doing he shortened the life of a patient dying from an incurable disease. But this, he felt, was entirely different from passing legislation on the subject. It would be a serious matter if for the first time there appeared on the statute book a law which gave certain people licence to kill some of their fellow men and women. Capital punishment was justified only because it was the vindication of the sacredness of human life. If once legislation of this kind was allowed where were we to stop? Why should it not apply to the feeble minded, the physically crippled, and those in mental asylums?

Lord HORDER hoped that the decision would not be with the doctor. Putting an end to human life involved a new principle in biological control, so foreign to the general sense of the community that he would be very surprised if it were accepted in Lord Chorley's lifetime, or ever. A good doctor, in Lord Dawson's words, distinguished between prolonging life and prolonging the act of dying. Any sanction which would reverse the doctor's function—to cure the patient's disease or prolong his life so far as might be—would not be in the public interest.

Turning to the criteria laid down by euthanasia advocates Lord Horder pointed out that the disease which was incurable today might be cured next year. Again the threshold of pain varied enormously in different patients and only the experienced doctor could judge how much pain was being suffered. There had never been so many means of alleviating pain as today. Illness, and even pain, for many people constituted a new experience, unhappy, but possessing spiritual significance and value. To call the function of a doctor who helped a patient to achieve that degree of elevation of spirit an intolerable burden seemed to Lord Horder to be disparaging one of the very important duties that a doctor had to perform. The two extremes of dying in pain and being killed did not exhaust the possibilities of the stricken patient. There was a middle position achieved again and again by a kindly and skilful doctor who gave assistance to a fellow human being who had become an intimate friend. A further criterion was that the patient must be of sound mind, but there was no less difficulty in judging the patient's state of mind than in assessing the amount of his pain and the incurability of his disease. The mind of the patient suffering from a lethal illness was not unsound in a legal sense, but it was uncertain and fitful, variable, and with little certainty or clearness of purpose. If euthanasia were introduced Lord Horder feared that old people might avail themselves of it, or think they ought to do so, because they felt they were encumbering the ground and would like to make room for someone else.

Lord AMULREE pointed out the change that a law of this sort would make in the atmosphere of the sick-room. At present the patient was convinced that the doctors and nurses were doing their best to alleviate

his pain. If a patient felt that one day the doctor would come in as executioner, even though the patient might long to end his life himself because of pain, Lord Amulree did not think that it would lead to an improvement in the relations between doctor and patient. Lord UVEDALE held that there were few cases at present where euthanasia should be contemplated, and these cases would become fewer still as new remedies were introduced. The matter should be approached with great caution remembering with all humility that euthanasia was an admission of failure and a counsel of despair.

Lord HADEN-GUEST reported that at the meeting of the World Medical Association in Scandinavia this spring a resolution was passed against euthanasia. The association represented doctors from every country in the world which chose to send delegates, and he thought it might be said that the vast majority of medical opinion in the whole world was against euthanasia. The vast majority of doctors in this country felt that whoever else was going to administer euthanasia, it was not they. The suggestion that the business of euthanasia should be put in their hands, that they should meet round the bedside of a patient and give him some injection to cause death, was to them a dishonourable suggestion.

Lord WEBB JOHNSON also thought the idea of euthanasia was dreadful when one had spent a lifetime in taking risks to save human life. He cited instances of several incurable diseases which had lately become curable. Were they to contemplate the situation in the sick-room where an elderly patient with a chronic illness looked round with suspicion and accepted every suggestion such as "How can you bear all this?" or "Don't you wish it was over?" as a suggestion that he should apply for the appropriate form and fill it in? Moreover, suppose, quite clearly on his own initiative, the patient put forward a request for release, was not to agree to that request legalising suicide? Lord Webb Johnson thought it was.

Lord JOWITT, the Lord Chancellor, said that from the legal point of view the consequences of passing a Bill of this kind would be grave and serious. The doctrine of what was called putting people out of their misery for the reasons which had been advanced might have serious repercussions on the criminal law of the land. The introduction of a Bill, no matter what the safeguards might be, would be wrong, because there could be no adequate safeguards when they allowed one human being to start killing another. Once they departed from the doctrine of the sanctity of human life they would indeed be on the slippery slope.

QUESTION TIME

Registrar Appointments

Mr J K VAUGHAN MORGAN asked the Minister of Health whether he would withdraw his proposals for an immediate cut in hospital registrar establishments with a view to putting forward an alternative scheme which would cause less hardship to those concerned, particularly those trainees whose careers had already been seriously affected by their war service.

—Mr A BEVAN replied. This circular which has been grossly misrepresented was issued after full consultation with the profession's representatives. Its object is in the interests of the profession itself—to secure a proper relationship between the numbers of training posts for future specialists and the number of specialist posts likely to be available. In estimating the latter it allows for a reasonable annual expansion over and above mere replacements in present posts, and the numbers of training posts will be reviewed as and when further expansion occurs in later years. The urgency of the circular is that the number of trainees has already risen to nearly twice the number needed to produce the specialists likely to be required and about four times the pre-war number. A situation thoroughly unfair to all concerned. The circular was not prompted by economy—indeed it provides for alternative appointments if necessary for the work of the hospital.

Mr VAUGHAN MORGAN. What prospects of suitable employment are open to those 1100 hospital registrars who would become redundant as the result of the proposed cut in establishment over and above the 700 appointments which are vacant in the Services and Colonial Medical Services.

—Mr BEVAN. Each existing senior registrar and registrar will complete his present year of appointment. Afterwards

PETHIDINE AND THIOPENTONE

SIR,—The use of pethidine hydrochloride as an adjunct to nitrous oxide anaesthesia is becoming increasingly popular, and I should like to draw the attention of potential users of this technique to the incompatibility of pethidine hydrochloride solutions with those of thiopentone sodium.

Presumably owing to the marked difference in pH between the two solutions, a precipitate forms upon mixing. If it is desired to follow the injection of thiopentone sodium with pethidine hydrochloride, untoward effects can be obviated by washing the apparatus, including the Gordh needle if used, with normal saline solution, before injecting pethidine hydrochloride.

CONSCIOUSNESS WITH VENTRICULAR FIBRILLATION

SIR,—We should be very grateful if any of your readers would give us information about the duration of consciousness after the onset of ventricular fibrillation. This point arises in connection with the killing of dogs and cats by electricity. In this procedure the current is passed from the neck to the hind quarters, not through the brain, and death is believed to be due to ventricular fibrillation. Observations on the duration of consciousness after ventricular arrest in Stokes Adams attacks would also be of great interest. Any communication reaching us will be most gratefully acknowledged.

F JEAN VINTER
Technical Secretary

Universities Federation for Animal Welfare
284 Regent's Park Road London N3

ENURESIS AND HYPERSOMNIA

SIR,—In your issue of July 22, Dr Ström Olsen points out that in adults enuresis may be associated with deep sleep.

For a number of years I have been aware of this, and accordingly I have been treating my enuretics with compounds of the ephedrine or amphetamine type, with gratifying results. I started using this kind of treatment after reading the chapter on sleep by Dr Regelsberger in the German *Encyclopaedia of Modern Medicine* (Spanish translation, 1935). He had found that in enuretics the curve of alveolar carbon dioxide reaches its peak (which is abnormally high) at the time of involuntary micturition. In the same book Nassau mentions the relation of nocturnal enuresis with abnormally deep sleep.

Madrid

EMILIO DE LA PEÑA

SCORPION STINGS

SIR,—Aly, Abul-Fadl, and Roushdy¹ have reported on the use of various substances against scorpion venom. In common with these workers, we were prompted by the letter of McSorley and Perry² to ascertain the effect of emetine on animals envenomated with scorpion venom. At the same time various other substances with alleged antidotal action were tested. Some of the results, which support the findings of Aly et al., were mentioned in the annual report of this institute for the year 1949.

The venom used was obtained from South African members of the genus *parabuthus*, the experimental animals were guinea-pigs and mice, the substances tested were emetine, atropine, adrenaline, procaine, ergotamine, dihydroergotamine, calcium gluconate, di-mercaprol (BAL), anti-histamine ('Histostab,' Boots). Combinations of atropine with either dihydroergotamine or anti-histamine were also tried. The survival rate and

survival time of the treated animals and the controls did not differ significantly. Atropine suppressed both the secretion from the respiratory passage and the salivation, and procaine abolished the severe pain, otherwise the symptoms of envenomation were not altered.

Abuja and Brooks³ have shown, and Christensen and de Waal⁴ confirmed, that local infiltration with a carbolic soap solution offers some protection against cobra venom. We have since found that guinea-pigs which have received an LD₅₀ of parabuthus venom in the muscle of a hind leg and which subsequently are treated by infiltration of the site with a 5% solution of carbolic soap in water stand a significantly better chance of survival than untreated controls.

We should like to add that all the substances mentioned, with the exception of soap, were also tested against spider (*Lactrodectus indistinctus*) venom in mice and were found to be useless. That calcium gluconate failed is of interest as it apparently has beneficial effect in treating spider bite in man.

STUDY OF DELINQUENCY

SIR,—May I add my voice to Dr Bodman's criticism of Dr Stott's curiously biased Study of Delinquency in your issue of Nov 25. Dr Stott writes with a very large bee in his bonnet, but with Dr Bodman I will be charitable and suggest that his experience appears to be "strangely limited." Such tendentious statements as "Neither the public nor the State have yet begun seriously to deal with the child in his pre-delinquent phases. Public concern is limited to punishing him when he dares to force his unhappiness [sic] upon us," and "Quite unnecessarily we allow unhappy children to remain unhappy" may be good propaganda, but they are a bad basis for a scientific study.

Dr Bodman last week took up the more obvious prejudices in the article. These I will not repeat, but I would note some other omissions. My experience at a child guidance clinic over the past ten years is that the good teacher needs no special training to spot "the unhappy child and potential delinquent." He (or more often she) is only too pleased to use the local facilities. One would think that Dr Stott had never heard of the now 20 year old child guidance movement, and knew nothing of the technique of examination and treatment at a child guidance clinic. Not that facilities are all they might be, but I am afraid Dr Stott's approach will not endear him to our administrators and make it any easier to extend them.

Dr Stott seems to have been very unlucky in his strange clinical contacts. His cases make quaint reading. But anyone can give odd examples of this kind, and I rather suspect him to be putting up aunt-sallies to knock them down. I will not comment on his psychological views except to note that amongst a great deal of shrewd observation there is much vague theorising and angry prejudice.

In conclusion I would quote Dr Stott's own remarks against himself: "But before we can press these points we must convince the public that the psychologist can deliver the goods." Let Dr Stott try his hand for a number of years at treating his delinquents in the social environment in which they are to live subsequently. He may find the experience not a little chastening, and discover that to make wild comments as a result of a research on some approved school types is much easier than to deliver the therapeutic goods to the public.

Leeds

II EDELSTON

¹ Aly M, Abul-Fadl, M, A M, Roushdy, M. *Lancet* 1950 1 1135
² McSorley J G A, Perry L M. *Ibid* 1949 1 889

³ Abuja M I, Brooks, A G. *Indian med Gaz* 1945 80 461
⁴ Christensen P A, de Waal M. *S Afr med J* 1947 21 680

Like many great men he was simple in his tastes and modest to the point of self-effacement. However, this did not prevent his great gifts and kindly wisdom being sought in the service of many bodies, both lay and professional. He represented Queen's University on the General Medical Council. He was elected president of the Northern Ireland branch of the British Medical Association in 1932 and of the Irish Medical Schools and Graduates' Association in 1936. In the following year he was elected president of the Ulster Medical Society. In 1948 he became a Deputy Lieutenant for the city of Belfast.

As a member of the Northern Ireland Hospitals Authority, Thomson worked without sparing himself to extend and improve the hospital and specialist services to which he had already contributed much of lasting value, and his fellow members have sent us the following tribute: "At all times Sir William's courtly manner, his innate kindness, and his invariable charm and good humour earned our love and confidence. In counsel he was wise and resourceful in discussion calm, courteous, and considerate, in difficulty helpful and courageous, and at all times unselfish, gracious and sincere. His integrity was a beacon to light the way to truth and his example was a great encouragement to all who lacked his long experience and wide knowledge."

In the last years of his life came his two final honours—a knighthood and election to the presidency of the Association of Physicians of Great Britain and Ireland, which set the seal on his professional career. "As Thomson never paraded his achievements," writes R. S. A., "many of the generations of students that he taught were only vaguely aware of the detailed brilliance of this great physician and scholar. To all of them, however, will remain the vivid memory of a kind friend and wise counsellor who was never too busy to spare the time to greet, and if need be, help with his wise advice any who came to him for it. In the examination and treatment of patients this human outlook was able to balance his professional genius with the real insight into human nature without which medicine, at any time, loses more than half its value."

Thomson lived opposite the university campus, and he and his wife, formerly Miss Josephine Barron, kept open house for all. "Lady Thomson" writes a friend, "helped in his career more than most people knew. When he was incapacitated for three years by ulcerative colitis all the medical pundits said he would neither practise nor teach again, but Lady Thomson defied them, and he did." Their only child, Captain Humphrey Thomson, R.A.M.C., was killed during the Burma campaign, when he insisted on remaining with patients who were too ill to be moved when his hospital was evacuated.

J. H. B. writes: "Brilliant as his achievements have been as counsellor, administrator, physician, and teacher, it was as a man that Thomson appealed to all of us. He possessed a genuine charm, he was so essentially human, he treated his colleagues with an old-world courtesy and he showed that curious blend of learning and culture which is oft-times developed in the good physician. The type of physician changes somewhat with the passing of generations, and many of us have felt that W. W. D. was one of the last of the Oslerian school. Like Osler, too, he was successful in the cultivation of such a measure of equanimity as enabled him to bear success with humility, the affection of his friends without pride, and to be ready when the day of sorrow and grief came—and as with Osler it came in the loss of an only son on the field of battle—to meet it with courage. All of us feel that he had found the answer to the prayer of Socrates for beauty in the inward soul and for unity of the outer and the inner man.

"His charity will be missed in the wards, his knowledge in the Faculty, his wisdom in the Senate, and his humanity by all."

ALEXANDER LOW

M.A., M.D., LL.D. ABERD.

Dr Alexander Low, emeritus regius professor of anatomy in the University of Aberdeen, died on Nov. 15 at the age of 82.

He was born at Oldmachar in Aberdeenshire, where his father was a farmer. From Aberdeen Grammar School

he entered Aberdeen University in 1886, and after taking his M.A. in 1891 he went on to take his medical degree, qualifying in 1894. He continued his studies at the universities of Freiburg, Vienna, and Zurich before joining the staff of the anatomy department at Aberdeen as assistant, later holding the posts of lecturer and reader. In 1912 he took his M.D. degree with highest honours. In 1925 he was appointed to the chair, and the university later conferred on him the honorary degree of LL.D.

G. A. G. M. writes: "Alexander Low's outstanding characteristics were gentleness and a modesty amounting almost to diffidence. It may be that his own congenital limb defect made him more sensitive to the failings, both physical and mental, of others, and that he was in consequence gentle and considerate to an unusual degree. However this may be, Low attracted to himself a depth of affection that was remarkable. He was a perfect example of the man who prefers to do good by stealth and who is embarrassed by its discovery, and not a few poor students during the past fifty years have benefited from his unostentatious help.

"All his long and active professional life was spent in the service of Aberdeen University, but he was so retiring and modest in all he said and did that it is perhaps not surprising that his true academic merits were sometimes better appreciated beyond the confines of his own school. In his earlier and formative years he spent several long vacations studying and investigating anatomy in Continental laboratories, and he had an enviable knowledge of German language and literature which he placed freely at the service of his more ignorant colleagues. His life work was coloured by his contacts with the embryological and anthropological giants of these days and his chief interests always lay in embryology and anthropology, a fact reflected in his publications.

"His researches were careful and polished, and anything he did such as his work on the development of the mandible and the arrangement of fibres in the diaphragm has survived almost intact the investigations of later workers. An acknowledged authority on remains of the Neolithic and Bronze Age periods, he had also been engaged for years in extensive anthropometric and other investigations of growing infants and of problems connected with twinning. After his retirement, he continued this work, often under great difficulties, especially during the war years. Most of his results are unpublished, but as similar figures concerning the growth of infants during the first 5-6 years of life probably do not exist, it is to be hoped that somehow they will not be lost.

"The twilight of Low's long life was burdened by increasing and trying infirmities, and the many who respected him so deeply are relieved to know that his fine and generous spirit is free at last."

WE have to record the death of a former member of our staff, Mr E. M. RYDER, who served THE LANCET for 42 years from 1892 to 1934. Besides acting as personal secretary to Sir Squire Sprigge, he was long responsible for the collection of material for the Students Guide, and for preparing New Inventions and New Preparations for the press. He had a talent for neat yet lucid description, as well as decided opinions on things and people, and if his manner sometimes intimidated his junior (and even senior) colleagues, it did not quite conceal his real affection for his chief and his care for the traditions of the journal. In leisure hours he was an interesting companion, whose mind remained alert to the end of his life. He died at his home at Wimbledon on Dec. 1, aged 83, and is survived by his daughter.

Appointments

CRICK R. P. F.R.C.S. D.O.M.S. asst. ophthalmic surgeon Royal Eye Hospital London.
FIELDING WILLIAM M.D. Manc. D.P.H. deputy M.O.H. Sheffield.
KERSLAKE D. M. M.D. Lond. human physiologist Royal Air Force Institute of Aviation Medicine South Farnborough Hants.
MARTIN K. W. M.B. Lond. F.R.C.S. senior registrar St. Peter's and St. Paul's Hospitals London.
NEWMAN M.B. D.P.H. asst. M.O.H. Hove Sussex.
TINKER CECIL M.D. Lond. M.R.C.P. senior registrar Lancaster House Chest Clinic Southend-on-Sea Essex.

a senior registrar whose appointment is not renewed but whose services are still needed may be offered a similar temporary hospital appointment for one year. Others and registrars can—as has always been the case where appointments in these training grades have not been renewed—apply to set up in general practice, possibly supplemented by a part time clinical assistantship at a hospital, or for appointments in civilian medical practice in this country as well as in the fields referred to by the hon. Member, or for university and hospital appointments abroad.

Replying to Mr. Henry Brooke, Mr. Bevan said that the number of posts of registrar and senior registrar which would be abolished in hospitals in the North West Metropolitan region if his recent circular was fully implemented was about 240 and 290 respectively (including the figures for the teaching hospitals in the area).

Beds in Tuberculosis Sanatoria

Mr. SOMERVILLE HASTINGS asked the Minister what was the number of beds reserved for the treatment of pulmonary tuberculosis in sanatoria, general hospitals, and fever hospitals, respectively, which were now empty because of shortage of nursing and domestic staff, what was the number of beds at present reserved for the treatment of pulmonary tuberculosis in sanatoria, general hospitals, and fever hospitals, respectively—Mr. BEVAN replied. The number of tuberculosis beds provided in institutions classed as sanatoria and tuberculosis hospitals is about 27,700, of which about 4,400 are unstaffed. There are some 3,500 staffed tuberculosis beds in other hospitals. Of the 31,200 staffed beds approximately 27,200 are for pulmonary and 4,000 for non pulmonary tuberculosis.

Service Pay

In answer to a question, Mr. EMANUEL SHINWELL stated that increases in pay had been approved for medical and dental officers of the three Services. In addition there will be increases in specialist pay for medical and dental specialists in the Royal Navy and Army, in the Royal Air Force specialist qualifications will continue to be recognised by a system of accelerated promotion. The increased rates will not apply to National Service officers until they have completed 18 months' whole time service. The increases and new rates, which will take effect from Sept. 1, 1950, are as follows:

BASIC PAY

Rank (only Army ranks shown)	Increases		New rates					
			Medical officers			Dental officers		
	Daily	Annual	Daily	Annual	Daily	Daily	Annual	Annual

National Service Medical Exemptions

In answer to a question Mr. G. A. ISAACS, Minister of Labour, said the numbers of men exempted from national service on medical grounds from 1946 to 1949 and those exempted this year were as follows:

Year	Number exempted from National Service on medical grounds*
1946	39,061
1947	24,048
1948	24,711
1949	33,818
1950 (to Sept. 28)	34,506

* Excluding men not examined—e.g. the blind and lame.

Obituary

WILLIAM WILLIS DALZIEL THOMSON

KT, B.A., M.D., B.Sc. Belf., FRCP

Sir William Thomson, professor of medicine in Queen's University, Belfast, and its representative on the General Medical Council, died on Nov. 20, at the age of 65.

A son of the late Dr. W. Thomson, J.P., of Anahill House, Hillsborough, co. Down, he was educated at Campbell College, Belfast, and later at the Queen's University. The whole of his academic career was a succession of brilliant achievements. In 1906 he won the Henry Hutchinson Stewart scholarship of the Royal University of Ireland, and in the following year, after gaining the Dunville studentship and senior scholarship in chemistry at Queen's University, he graduated B.A. with first-class honours. In 1919 he obtained his medical qualifications in Queen's, again with first-class honours, which then, as now, was a rare achievement.

His first teaching post at Queen's was in the physiology department, from which he went on to be Riddell demonstrator in pathology. During this period he added a B.Sc. to his name, again with first class honours. He travelled abroad and studied in Paris and Budapest. After this he carried on his research work while he was with the R.A.M.C. in the B.E.F., attached to Sir Almroth Wright's laboratory. Later he used to recall how in those early days they did blood transfusions without grouping. On soldiers suffering from trench nephritis the first blood ureas were done, and in these war years Thomson did the first series of blood-urea estimations in prostatic obstruction. He never published these, but his work on war nephritis appeared in 1918. In 1910 he had obtained an M.D. with gold medal, thus completing an academic career whose lustre has rarely if ever been equalled in the annals of Queen's University.

It was only natural that a man of his attainments should serve in the teaching of others and shortly after his return to Belfast, in 1923, he was appointed professor of medicine. Five years later he was elected a fellow of the Royal College of Physicians of London. He served on the staff of the Mater Hospital before his appointment as assistant physician to the Royal Victoria Hospital in 1918. He became full physician in 1923-24 when he was given charge of wards. He had the rare gift in teaching of making difficult subjects plain to those less gifted, and his clinical lectures and demonstrations in the Royal Victoria Hospital were always crowded with eager students.

Though serious illness which developed soon after he had been appointed professor, threatened for a time to cut short his career, he recovered and once more resumed his teaching and his hospital and private practice. Besides his work on war nephritis, he published papers on bronchial carcinoma and the renal aspects of essential hypertension. In 1939 he delivered the Lumenian lectures before the Royal College of Physicians, choosing as his subject Primary Carcinoma of the Lung.

(By wirephoto)

each of these three is the better for its association with the other two." The authors suggest that "in a satisfactory health service the family doctor should play an even more important part than in the past because the real battle for the child's health is fought in the home and the family doctor is most familiar with the social and environmental conditions." Furthermore health centres by providing for family doctors, school and child welfare clinics, health visitors, and district nurses, should promote co-operation between family doctors and local authority workers and thus enhance the efficiency of the child health service. The need for more and better buildings in this region (as in most) is clamant but "though better buildings are needed the doctors and nurses and their helpers are more important than the walls within which they work." This well balanced survey will doubtless be the forerunner of others.

University of Cambridge

The Raymond Horton-Smith prize for 1949-50 has been awarded to Dr A. G. E. Pearse, Trinity College, for his essay on Cytochemistry and Secretory Cytology of the Anterior Hypophysis. Dr B. G. Parsons-Smith, Trinity College, was the runner up with an essay on the Value of Electro-encephalographic Study in Cases of Cerebral Tumour.

University of London

The title of reader in anatomy in the university has been conferred on Dr R. J. Harrison in respect of his post at Charing Cross Hospital Medical School.

Royal College of Surgeons of England

A series of exhibitions and demonstrations are being held in the college on Dec. 13 the day of the annual meeting of fellows and members. In the department of physiology there will be an exhibition and demonstration of the scientific equipment and the department of pathology will show recently acquired specimens illustrated by photomicrographs, microradiographs and radiographs including groups illustrating diseases of the vertebral column, treatment of malignant disease of the bony pelvis by hind quarter amputation, and visceral hydatid disease. The department of anatomy will also display recent specimens including dissections of the bunturing ("Whiskers" from the Zoo), the neck of the darter and the submandibular glands of the tamandua. New additions to the odontological collection will also be on view. Among research exhibits will be preparations showing the development of the ureter, the comparative anatomy and physiology of the subepithelial system and human lungs injected with Marco resin, together with models showing the development of the lung of a child. The general department will show some of the college plate and a selection of the illuminated addresses presented in connection with the 150th anniversary. In the library there will be shown recent acquisitions of historical and new books, gifts of autograph letters and bookplates, selections from the collection of engravings, and biographies of fellows. The exhibitions will be open from 2 p.m. onwards. Mr William Doolin will give the Thomas Vicary lecture at 4 p.m. and the meeting of fellows and members will be held at 5.30 p.m.

Infectious Tuberculosis in London

The Minister of Health has approved in principle the provision by London County Council of hostel accommodation for people with tuberculosis who are infectious but are unlikely to benefit by further sanatorium treatment and who have either no home or no suitable home. The Minister's approval is given on the understanding that the cost shall not increase the Council's total expenditure under Part III of the National Health Service Act. Earlier the Minister rejected a plan to construct on the site of St. Peter's Hospital, Stepney, a night sanatorium and industrial workshops (see *Lancet* Oct. 25, 1950, p. 491).

Supplies of Aureomycin

A plant for the production of 'Aureomycin' is nearing completion at Hirwaun, South Wales. At this plant, which is being built by the Lederle Laboratories division of Cyanamid Products Ltd., work will be confined to purifying crude aureomycin and encapsulating and packaging the refined product. Production is expected to satisfy domestic demands as well as providing for exports. The company is investigating the possibility of creating in Britain a plant for the complete manufacture of this antibiotic.

Royal Society

On Nov. 30 Prof. E. D. Adrian, O.M., was elected president of the society.

Professor Adrian became president on his 61st birthday. He has held the Foulerton research professorship of the society and he is professor of physiology in the University of Cambridge where except for his hospital work at Barts as a student and his service in world war I, he has worked since his student days. A pupil of the late Dr. Keith Lucas, he has continued and amplified the work of that pioneer in neurophysiology and he was awarded the Nobel prize in medicine in 1932. For many years he has served on the committee of the Physiological Society; he has acted as its secretary for 3 years and he was editor of the *Journal of Physiology* for 10 years. In 1942 he was appointed to the Order of Merit. His other distinctions include the Royal medal (1934), the Copley medal (1946), the Croonian lecture-ship (1931), the Ferrier lectureship (1938), and the Baly medal (1929). His published papers deal mostly with the properties of nerve fibres and with investigations on the central nervous system. Electro-encephalography rests almost entirely on his fundamental investigations and he was largely responsible for the development of techniques by which the passage of the sensory impulses may be traced from the sensory nerve-endings to the cerebral cortex.

Dr I. de Burgh Daly, Prof. Wilson Smith, and Dr V. B. Wigglesworth were elected members of the council of the society.

Fluoride in Drinking-water

The American Water Works Association convention in Detroit was told by Dr. Chester Tossy that at Grand Rapids, Michigan, putting fluoride in the drinking water for the last six years had reduced dental caries by more than 60%. He also said, according to B.U.P., that within the next ten years most U.S. cities would be adding fluoride to their drinking water, the cost to each ratepayer was only about 2d a year. Dr. A. P. Black, of the University of Florida, suggested that fluorination of drinking water was the biggest step in public health in the last hundred years.

Beds in Swiss Sanatoriums

The members of the clinical team who will shortly visit Switzerland to study the medical facilities available there for the treatment of patients with pulmonary tuberculosis are Dr M. A. Foulis, physician superintendent, Robrovston Hospital, Glasgow, Dr R. Y. Keers, medical director, British Red Cross Sanatoria in Scotland, Miss G. M. M. Carter, matron, East Fortune Sanatorium, East Lothian, Dr I. M. Macgregor, medical officer, Department of Health for Scotland.

Their visit arises out of the preliminary inquiries into sanatoria facilities carried out by officers of the Department of Health for Scotland at the beginning of November. On their return Miss Margaret Herbison, joint parliamentary under-secretary of State for Scotland, announced that their report was sufficiently encouraging to justify a visit by clinical experts.

New Science Centre

In his farewell address as president of the Royal Society Sir Robert Robinson announced that the following scientific societies were taking part in the new centre: Biochemical Society, British Association, Chemical Society, Faraday Society, Geological Society, Linnean Society, London Mathematical Society, Physical Society, Physiological Society, Royal Anthropological Institute, Royal Astronomical Society, Royal Meteorological Society, Royal Society, Royal Statistical Society, Society of Chemical Industry. Many of the smaller scientific societies and clubs would continue to receive hospitality. "I am disappointed," he added, "that it is not possible for me to enlarge on the contribution which the science centre building should make to the aspect of the new London. Nor can I expatiate on the famous landmarks that may be visible from its windows. Suffice it to say that we believe the site, when finally selected and approved, will be found to be entirely satisfactory, not only in area but also in position. There is no doubt that it will offer a great opportunity to an imaginative architect and it will be easily accessible from other parts of London."

It is probable that the scientific societies will be housed in a worthy and impressive building such as one as could look Somerset House in the face and it is agreed that this will have the most prominent position on the site. The quarters for the various societies will be separate with their own entrances, very much in the same way as here at Burlington House. He hoped the tercentenary of the foundation of the Royal Society in 1660 would be celebrated in their new home.

Notes and News

HAZARDS OF FLUID THERAPY

ADDRESSING the Manchester Medical Society's section of medicine on Nov. 1, Dr D. A. K. Black referred to some of the dangers of indiscriminate treatment with intravenous fluids. Although the value of suitable treatment with saline or glucose solutions was well established, their use might also give rise to harmful effects, which were the more dangerous in that they might come on insidiously. Despite Marriott's work, saline fluid was still given when a non-saline fluid would be more appropriate, and vice versa. Clinically, a complaint of thirst should suggest predominant water depletion, and signs of peripheral circulatory failure predominant salt depletion. The estimation of serum sodium was the most direct biochemical method of distinguishing between salt and water depletion. The test for urinary chloride might be misleading in the presence of acidosis or alkalosis, or of renal or suprarenal disease.

Apart from giving the wrong type of fluid, it was also possible to give excessive amounts of the correct type of fluid. This was well appreciated with saline fluid, but the dangers of excessive intake of watery fluid were less well known. In anaemia it was essential to restrict the intake of water as well as of salt, and there was also a risk of water intoxication in the period following surgical operations, in which, as Coller and his associates had shown, the elimination of water was seriously impaired. There was a danger of producing significant acidosis when large amounts of normal saline were given to correct salt depletion. In severe salt depletion it was better to give a fifth of the required sodium as lactate. When alkalosis was caused by excessive alkali administration ammonium chloride could safely be given, but when alkalosis was due to vomiting, it was associated with salt depletion, and normal saline was more suitable than ammonium chloride. A low alkali reserve might be due to respiratory alkalosis, and not to metabolic acidosis, for example in salicylate poisoning; the low alkali reserve was a sign of respiratory alkalosis, and sodium bicarbonate might not be the best treatment. Caution was very necessary in the intravenous administration of potassium. Potassium infusions should be given very slowly, to avoid cardiac arrest, and the oral route was much to be preferred, whenever and as soon as practicable.

In conclusion, Dr Black disclaimed any wish to set up a new specialty of applied electrolyteology, and suggested that those undertaking fluid therapy should ask themselves three questions, which could often be answered clinically: (1) Do we need to give fluid at all? (2) Do we give saline or non-saline fluid? (3) Have we given enough, or too much, fluid? Healthy kidneys were a great help in correcting mistakes in fluid administration and after all most of the patients survived.

"UNESTABLISHED" GENERAL PRACTITIONERS

A WELL ATTENDED meeting of unestablished general practitioners took place in London on Nov. 29. Dr J. H. Edgar, who was in the chair, summarised a statement prepared by the committee which had arranged the meeting. Dr Edgar advocated reduction of the maximum size of lists to 3000 patients, an expenses allowance of £600 to form part of the remuneration of all general practitioners and removal of the restrictions on transfers. These proposals were designed to help the 'squatter' and other principals with small lists. He went on to say that the system of assistantships without a view to partnership should be abolished and meanwhile the conditions of employment of assistants should be safeguarded by Regulation. Lastly, he pointed out that doctors should be attracted to 'undesirable' areas by financial inducement, and not forced there by economic pressure. In the subsequent discussion two points were emphasised: (1) that the transfer regulation was an intolerable obstacle to the small list practitioner and the would-be principal; many speakers indicating that it had already caused them hardship, and (2) that the system of permanent assistantships without a view to partnership had no place in the National Health Service. Dr Edgar declared that the number of assistantships with a view had dropped to 60% of that in the previous year and that the intake of new patients by 'squatters' had fallen to 15% of the number prior to the transfer restrictions.

Dr Edgar, speaking on behalf of the organising committee, suggested that adequate representation of unestablished practitioners could best be achieved by the formation of a special group of the British Medical Association. In the discussion it became apparent that there were three arguments in favour of this: maintenance of the unity of the profession, simplicity of organisation and the possibility of direct representation on the General Medical Services Committee. Nevertheless, there was a definite body of opinion in favour of a separate association. A resolution for an application to the council of the British Medical Association for the formation of a special group was carried by a substantial majority.

SYRINGES FOR INSULIN INJECTION

A NEW British standard for hypodermic syringes for insulin injection has been published. This standard (B.S. 1619/1950) is based on the standard for hypodermic syringes for use in medical and surgical practice (B.S. 1263) and covers all glass as well as metal and glass syringes. The specification is designed to cater for the special requirements of diabetics who normally perform their own injections, and the scale is marked in twentieths of a millilitre, to enable them to estimate more readily their dosage requirements. Two sizes of syringe are given, with nominal capacities of 1 ml and 1½ ml. Dimensions of the conical tip are given exactly, being identical with, and interchangeable with, the American Luer tip (as in B.S. 1263). Copies of this standard may be obtained (price 2s. 6d.) from the sales department, British Standards Institution, 24 Victoria Street, London, S.W. 1.

BLINDNESS DUE TO HEREDITARY DISEASE

IN Norway Holst¹ has investigated the causes in 3181 cases of blindness. Among this total those who become blind in old age may not be fully represented, for members of this group are commonly overlooked, and this must be borne in mind in judging his observation that almost half (18%) of the 3181 cases were due to hereditary disease. Earlier surveys have suggested that hereditary disease is the cause in a much smaller proportion—one third or less. Holst's records of blindness due to hereditary disease include 10³ cases of congenital atrophy of the optic nerve, 263 of retinitis pigmentosa, 304 of congenital cataract, and 145 of glaucoma simplex. He is prepared to defend his inclusion of glaucoma simplex among the hereditary causes, but he is more diffident about including 33 cases of senile cataract. As regards prevention Holst remarks that Hitler's pseudo-scientific experiments in genetics may have spoiled the prospects of practical work in this field for a long time to come, but we must continue to face the possibility of sterilisation or a ban on the marriage of persons with a family history of hereditary blindness, taking each case on its merits. In Norway between 1945 and 1949 four women and one man were sterilised with a view to preventing blindness in the next generation. As for the non-hereditary cases, Holst draws attention to the importance of methanol which accounted for 42 of the 60 cases due to poisoning.

REGIONAL CHILD-HEALTH SURVEY

SOMETHING new in regional surveys has been undertaken by Prof. John Craig and Dr Joan Burrell. In their review of child life and health in the North Eastern (Aberdeen) Region of Scotland² they outline the paediatric services and with special reference to the year 1948, report on the children's health so far as this can be judged from official medical reports, hospital admissions and mortality rates. The region, with a population of 501,000, includes the island counties of Orkney and Shetland—isolated communities which contrast in many ways with the mainland area. One point that emerges from an analysis of the number of mental defectives in various parts of the region and of the facilities provided for them, is that only Aberdeen City gives adequate special education to the educable members of this group and that in all areas there is a lamentable lack of homes for the non-educable. An account of the development of the teaching of child health includes the observation that "teaching and research determine the character of the care of children and

ON CLINICAL MEDICINE*

F M R WALSH

M.D., D.Sc., F.R.C.P., F.R.S

CONSULTING PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL

TODAY student and practitioner of medicine live in a fast-changing world of medicine, and do not breathe the stable and peaceful air in which, some forty years ago, I took my infant steps in medicine.

Then, clinical medicine seemed a simple and all-embracing conception of our activities. To misuse some words of Tennison, "Her court was pure, Her reign serene," and we allowed ourselves only the venial infidelities of occasional excursions into a simple and limited clinical pathology, into what was called Public Health and Forensic Medicine, with some comic interludes—as we then thoughtlessly regarded them—into vaccination (to which no less than six lectures were devoted) and mental diseases, to which we gave as little time as we could. But with a fine sense of where our true love was to be found, namely, at the bedside or in the outpatient clinic, we did not allow these phylanderinges to distract us unduly from our allegiance to her.

Some of us still remain singleheartedly devoted to her, but we are a pathetic, a diminishing and, if the truth is to be told, a dilapidating band of ancient lovers wearing our archaic graces with a faintly ridiculous air.

The sad fact today is that clinical medicine, as we see her in that cosmopolitan crush known as the curriculum, is a damsel in distress with scarce a champion, her rights disputed by a growing band of bold faced competitors, each of whom is wooed and praised by a more oddly assorted band of suitors than ever sought the hand of Portia or Penelope. Their names are legion, industrial medicine, social medicine, psychological and psychosomatic medicine, geriatrics, and so on—bigger and better names than ever we knew of forty years ago. A new debutante is now with us. Her name is 'adaptation stress' and if we can be cajoled into making an honest woman of her, she will we may be sure, be the fertile mother of her own litter of specialists.

All these and more are—to change my metaphor—the new lamps for old with which persuasive magicians seek to seduce the medical Aladdin in his youth and innocence.

And if all this is tempting to us, what a brave new world it offers to the community. The citizen, from cradle to grave, and at the price of a weekly stamp, may hope to be accompanied on his harassed journey through life by relays of specialists: the obstetrician, the paediatrician, soon of course the pubertarian and the climacterician (subgroups of the species endocrinologist), and other experts in school and factory, until finally he declines, decrepit and exhausted, into the eager hands of the geriatrician and his sequent colleague the mortician, having enjoyed through all stages of the unequal contest a wide choice of psychiatric first aid.

There is I believe, a useful convention by which the paediatrician passes us on at the age of 12 to his successor on the medical conveyor belt in our Welfare State. When, I ask my trembling contemporaries, does the hour strike at which we are passed on to the geriatrician to have our old bones trained for the Olympian games?

If my remarks do not seem to you sufficiently serious in form for the occasion, I humbly submit that they are not without substance, for the state of affairs I have sketched is surely the logical conclusion of much modern talk and planning on medical services and medical education.

* The Schorstein lecture delivered at the London Hospital on October 19, 1950
0642

Nearly a century ago a wise man said that the nonsense talked on education outweighed all the other nonsenses put together, and suspecting that this aphorism contains more than a little of the truth where we are concerned, it has seemed to me worth while to trace the growth of clinical medicine since the age of Sydenham, to see what has happened to it and what we are making of it in the medical education and practice of today. Is the clinical method still as important as Sydenham believed it to be?

* * *

Modern clinical medicine owes its birth to Sydenham who bridged the long gap between the ancient and the modern medical worlds by a return to the Hippocratic discipline. This rebirth was virtually contemporary with that of physiology. What, in the 17th century, Harvey did for physiology by the method of experiment, Sydenham did for medicine by the introduction of clinical study.

These two sources of inspiration and method in medicine have now joined to make a mighty stream, but what I am suggesting is that those of us who are, or who intend to be, practising doctors, the clinical source is still the primary one.

As we trace the development of clinical medicine since its renaissance in the 17th century, we see the appearance of a succession of new insights, of new and often opposing schools of thought, each of them dominant for a time perhaps in one country more than in another, but then coalescing with earlier and with later influences to swell the main stream of medicine as we see it today.

Each new insight, each new method of approach seems to have made the progress of knowledge swerve from the course upon which it was set, and thus in virtue of the excess inherent in all new doctrines that have vitality and are expounded by men of force and genius, for there is an element of excess in all greatness.

The pendulum of doctrine has never ceased to swing, and those whose efforts have disturbed, while they have sped, the steady march of progress, have always been persuaded that they were putting medicine on its true and final course at last. The illusion of dogmatic finality is no monopoly of the theologian, but is an ineradicable element in the human mind.

The impression of a changing and unstable equilibrium which the history of modern medicine gives us, should perhaps make us charitable to, and patient with, some of the current enthusiasms and apparent aberrations of thought in medicine. Each of these contains its grain of truth, but not the whole truth, and partial truths not recognised as such, can be very dangerous.

What I shall call partial truth, or partial thinking is still our gravest danger in medicine, and, surrounded as we now are by a vast and growing mass of diverse information, it is scarcely surprising that this should be so.

Looked at from this point of view, the brief and incomplete story of clinical medicine in the past three hundred years which I now give, may have a lesson for us in our time.

* * *

It was Sydenham who gave to clinical medicine the place of honour as a scientific discipline which, in my submission, it has never lost. He sought by the direct study of sick persons to write a natural history of diseases. Abandoning the theories and the abstract systems of his predecessors, he set out to describe visible signs and symptoms with accuracy and precision, to form notions of their combinations and sequences in illness of different kinds and thus to form concepts of disease. He was the founder of nosography.

In this he displayed a fine clinical flair, an eye for the relevant and a capacity for discarding the irrelevant. Like all truly scientific observation, his was selective.

Royal Society of Medicine

On Dec 1, Lord Webb Johnson presented the Henry Hill Hickman medal to Dr R J Minnitt at a meeting of the anaesthetics section of the society

Medical Honour

The King has appointed Surgeon Lieutenant D S Macphail to be a member of the military division of the Order of the British Empire

"for courage skill and determination when he was dropped by parachute into Yugoslavia in May, 1944 and in spite of the very primitive conditions and the scarcity of medical supplies established a hospital for the Partisans"

Royal Sanitary Institute

The health congress of the institute will be held at Southport next year from April 23 to 27. The following presidents of sections have been appointed: Sir John Charles (preventive medicine), Prof T H Davey (tropical hygiene), Dr A Massey (hygiene in industry). Further particulars may be had from the Institute, 90, Buckingham Palace Road, London, S W 1

Manx Chemists

The 34 chemists on the Isle of Man who withdrew from the health service on Nov 13 have now accepted the prescription and container charges which were the cause of their dispute with the Health Services Board. It is understood that they have received an assurance that in future they will be given prior notice of any new regulations affecting the pharmaceutical service. The board's decision to debit 6d to the chemists' accounts for every prescription dispensed by them between Oct 1 and Nov 13 is to be the subject of negotiation. During the 18 days of the "strike," the 7 chemists who remained in the service dispensed about 150 prescriptions a day between them; these were collected and distributed by the police authorities.

Medical Inspectorate of Mines

Dr T E Howell has been appointed principal medical inspector of mines in succession to Dr S W Fisher, who has retired on reaching the age limit.

Dr Howell was born in 1900 near Risca, Monmouthshire and attended various village schools before serving with the Royal Air Force during the 1914-18 war. Before beginning to study medicine he worked for some years in the coal-mining industry and he obtained a first-class mine manager's certificate. In 1934 he qualified from Guy's Hospital and three years later took his M.B. Lond. After a period in general practice he returned to Guy's as registrar and chief clinical assistant to outpatients, at the same time holding the post of pathologist to the Evelina Hospital for Sick Children. In 1938 he joined the factory department of the Home Office as medical inspector of factories in charge of the south-western region. After five years during which time he was also lecturer in industrial medicine at Bristol University, he left the factory department to join the Ministry of Fuel and Power as deputy chief mines medical officer. For several months during 1946 he was loaned to the Ministry of Labour to deal with difficulties in connection with recruitment of miners for work in the Ruhr coal fields and he recently represented the Ministry at a congress of industrial medical officers in Vienna. His interests, apart from his work, are animal genetics and farming.

Births, Marriages, and Deaths**BIRTHS**

BAILIE—On Nov 29 in Belfast, the wife of Mr H W C Bailie F.R.C.S.—a son.
CLAREMONT—On Nov 29 in London the wife of Dr Hugh Claremont—a son.
GLADSTONE—On Nov 27 at Woodstock, the wife of Dr G P Gladstone—a daughter.
HADFIELD—On Nov 24 in London the wife of Dr Gordon Hadfield—a daughter.
LAUBER—On Nov 24 in London the wife of Dr H C Lauber—a son.
POMFRET—On Dec 2 at Southsea the wife of Surgeon Captain A A Pomfret O.B.E. R.N.—a son.

MARRIAGES

MANSON BAIR—GROSSMITH—On Nov 23 at Tandridge Sir Philip Manson Bair M.D. to Edith Mary Grossmith.
NEWTON—ROSLANES—On Nov 23 at Brockham Green William Boyd Newton M.D. to Sheila Margaret Stewart Romanes.
SMELT—KNIGHT—On Nov 23 at Warlington Hants Charles Michael Casterton Smelt captain R.A.M.C. to Joan Anne Rosemary Knight.
WARLOW—OAKLEY—On Dec 2 in London Allan Llewellyn Warlow M.R.C.S. to Joan Astrid Oakley.

DEATHS

BARFORD—On Nov 29 James Leslie Barford M.R.C.S. D.P.M.
DEMPSEY—On Nov 25 in Dublin Timothy Gerard Dempsey M.B. U.I.
EVANS—On Nov 26 Jessie Downie Granger Evans M.D. Lausanne.
HUTCHINSON—On Dec 2, at Bury Lancs Gladys Hilda Hutchinson M.B. Manc.

Diary of the Week

DEC 10 TO 16

Monday, 11th

MEDICAL SOCIETY OF LONDON 11, Chandos Street Cavendish Square W 1
8 30 P.M. Pathological meeting
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28 Portland Place W 1
4 30 P.M. Sir Leonard Parsons F.R.S. Historical Background the Unborn Child (First Harben lecture)

Tuesday, 12th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5 30 P.M. (London School of Hygiene Keppel Street W C 1)
Dr K W Donald Definition and Assessment of Respiratory Function (First lecture)
CHELSEA CLINICAL SOCIETY
7 P.M. (47 Queen's Gate Terrace S W 7) The Very Rev Hewlett Johnson, D.D. Health and Education East of the Iron Curtain
INSTITUTE OF DERMATOLOGY St John's Hospital Lisle Street, W C 2
5 P.M. Dr J O Oliver Pathology
CIBA FOUNDATION 41 Portland Place, W 1
5 P.M. Sir Stanton Hicks The Role of Suprarenal Cortex in Function in Disorders of Childhood
PADDINGTON MEDICAL SOCIETY
8 30 P.M. (St Mary's Hospital W 2) Prof C A Pannett Restraint in Surgery
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE
4 30 P.M. Sir Leonard Parsons The Newborn Child and the Infant (Second Harben lecture)
EDINBURGH POST GRADUATE BOARD FOR MEDICINE
5 P.M. (Edinburgh University Anatomy Theatre) Prof. H L Sheehan Renal Cortical Necrosis

Wednesday, 13th

ROYAL COLLEGE OF SURGEONS Lincoln's Inn Fields W C 2
4 P.M. Mr William Doolin Dublin's Surgeon Anatomist (Thomas Vicary lecture)
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE
4 30 P.M. Sir Leonard Parsons The Older Child a Glance into the Future (Last Harben lecture)
INSTITUTE OF DERMATOLOGY
5 P.M. Dr C W McKenny X-ray Technique
ASSOCIATION OF SEA AND AIR PORT HEALTH AUTHORITIES
11 30 A.M. (90 Buckingham Palace Road S W 1) Dr M J Lennox Publicity and Port Health
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW
242 St Vincent Street Glasgow C 2
5 P.M. Professor Sheehan Renal Cortical Necrosis (Well lecture)

Thursday, 14th

ROYAL COLLEGE OF SURGEONS
3 P.M. Prof L Witts Ocular Aspects of Blood Dyscrasias
UNIVERSITY OF LONDON, Senate House W C 1
5 30 P.M. Sir Stanton Hicks Food and Folly (Sanderson Wells lecture)
BRITISH POSTGRADUATE MEDICAL FEDERATION
5 P.M. Dr Donald Definition and Assessment of Respiratory Function (Second lecture)
ST GEORGE'S HOSPITAL MEDICAL SCHOOL Hyde Park Corner S W 1
4 30 P.M. Dr Anthony Felling Neurology lecture-demonstration
INSTITUTE OF DERMATOLOGY
5 P.M. Dr E J Moynahan Bites and Stings
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE 26 Portland Place W 1
7 30 P.M. Dr J R Andy Scrub Typhus in Burma and Malaya
ALFRED ADLER MEDICAL SOCIETY
8 P.M. (11 Chandos Street W 1) Dr Edward F Griffith Initiation
LONDON JEWISH HOSPITAL MEDICAL SOCIETY, Stepney Green E 1
3 P.M. Clinical meeting
LIVERPOOL MEDICAL INSTITUTION 114 Mount Pleasant, Liverpool 3
8 P.M. Dr R E Rewell Pathology of Captive Wild Animals
TORQUAY AND DISTRICT MEDICAL SOCIETY
8 30 P.M. (Torbay Hospital Torquay) Mr Norman Lake Surgical Aspects of Hypertension
HONYMAN GILLESPIE LECTURE
5 P.M. (Edinburgh University Anatomy Theatre) Dr J C McCrie Reflections from a Provincial Deanery

Friday, 15th

MAIDA VALE HOSPITAL MEDICAL SCHOOL Maida Vale W 9
5 P.M. Mr Valentino Logue Clinical neurological demonstration
INSTITUTE OF OPHTHALMOLOGY Judd Street W C 1
5 30 P.M. Mr G I Scott Clinical Perimetry
BIOCHEMICAL SOCIETY
2 P.M. (Department of Biochemistry and Chemistry Medical College St Bartholomew's Hospital F C 1) Short papers
UNIVERSITY OF EDINBURGH New Buildings Teviot Place Edinburgh 8
2 30 P.M. Prof Ian Aird Surgical Exposure of the Pancreas (MacArthur lecture)
FACULTY OF RADIOLOGISTS
2 15 P.M. Diagnosis Section (Royal College of Surgeons) Dr R A Kemp Harper Mr I G Williams Thyroid Tumour in Myasthenia Gravis

Saturday, 16th

ASSOCIATION OF BRITISH NEUROLOGISTS
10 A.M. (National Hospital Queen Square W C 1) Dr F C Lumsden Basic Problems in the Pathology of Disseminated Sclerosis and Demyelinating Disease (First Florence Tong lecture)

In a measure these German enthusiasts were right when they declined to accept a "disease" as a natural entity, as something in nature. In nature there are for the practising doctor only sick persons, and the composite average picture of disease we construct from the study of like illnesses in different persons is not something concrete, but simply a mental construct, and what the German physiological school was rejecting was what has been called "the fallacy of misplaced concreteness." Yet in exposing a logical error in current notions, they went too far when they denied the specific characters of many different illnesses which the insight of their predecessors had identified. In popular language, they threw out the baby with the bath water—as enthusiastic reformers are so apt to do—and failed to realise that descriptions of different forms of illness, nosography, remains and must always remain essential to the clinician.

Nevertheless, this physiological epoch in the medicine of the 19th century, incomplete as were its insights, was a great, nay an essential, step in the forward growth of medicine, and it had the additional and priceless merit that it saw the introduction of the experimental method in medicine.

Yet, here also, history repeated itself, and once more an outlook that transformed the face of medicine came in a measure, and for a time, to distort perspective, as when Virchow, ignoring the art of medicine, proposed that practical medicine should become applied theoretical medicine. Under his influence, the strength of which it is now difficult for us to appreciate who have no towering figures in medicine comparable with the giants of 90 or 100 years ago, the clinical method and nosography in general became disparaged, its progress delayed and the art of medicine ignored. I sometimes think that even yet the clinician has not wholly regained that pride in his discipline which its exacting nature and its record of achievements demand, and is prone to accept too easily and to apply uncritically the facts he is offered from the experimental laboratory.

The same attitude towards the clinical method was shown by Claude Bernard in France when he invited the physician to desert the bedside for the laboratory in his search for knowledge, since he—as many lesser men since—believed the clinical method of study was worked out like an exhausted vein of precious metal in a mine.

Yet while Virchow and Bernard were writing obituaries of the clinical method, Charcot and Trousseau in France and Hughlings Jackson and others in this country were still demonstrating what the clinical method could achieve not only in nosography, but also in the philosophic understanding of normal and disease processes. After all, the clinician is perhaps the best judge of the usefulness of his methods.

Trousseau, indeed it was, who made one of the first steps in the next essential condition of advance in medicine, when he proposed "that what gives the specific diseases their immutable properties is not the quantity but the quality of the morbid cause" thus opening the stage of aetiological inquiry in medicine. To each particular cause of disease the system reacts with specific and characteristic phenomena. In other words, when we endeavour to construct typical clinical pictures we are taking a first step to track down some specific pathological cause.

At the time of Trousseau's death in 1867, Pasteur was engaged upon brilliant studies of the cause of fermentation and putrefaction—the fruit of which was to establish that many diseases were reactions to specific micro organisms, and bacteriology was born.

Neither time nor your patience would allow me to discourse upon the revolutionary influence of what has been called the germ theory of disease upon medicine.

My point rather is that this also, by its very success, tended to give a too exclusive outlook to the generation in which it developed and achieved its so striking triumphs.

Causation in disease was a larger and more complex problem than had yet been envisaged, and was the subject of a great deal of partial thinking—still current amongst us in those simple souls who like to see in chronic and obscure ill health the work of that nebulous concept "focal infection." A cynic has said that to "find a germ and stop thinking" is still the preoccupation of too many amongst us.

We have, in fact, forgotten Aristotle and his four orders of causation—material, formal, efficient, and final—and we are painfully relearning them in a terminology of our own, too often without realising that it is only a process of rediscovery.

In short, intemperate enthusiasms of doctrine still sway us, and perhaps never more than now when we see psychiatry and psychosomatic medicine running neck and neck, each seeking to become the master notion in modern medicine.

* * *

We have seen, then, in our time the progressive widening of our notions of causation, of aetiology, in disease. To bacteriology have been added insights derived from chemistry, biochemistry, and now physics, and from the intermittent and often smoky light of psychology.

From all this mass of knowledge, a more philosophic notion of causation is taking shape, and has found expression with admirable lucidity and conciseness in a paper by Dr J. L. Halliday, entitled *Principles of Aetiology*, published in the *British Journal of Medical Psychology* in 1943. I could wish that this paper were far more widely known, for it is the best synthesis of a complex problem that I have met, and should be an admirable corrective to those recurrent accessions of dogmatic and partial thinking which, generation after generation, have disturbed the steady and rational process of growth in medicine.

A stage has now been reached when we realise that we have become increasingly dependent in medicine upon the application of biological and physical science to the solution of our problems. To take but a few obvious examples—the value of the X ray film in the diagnosis of carcinoma of the lung, and its application of arteriography in the detection of intracranial aneurysm, and those blood and body fluid examinations of almost infinite diversity which are needed for the elucidation of problems that clinical observation raises but cannot by itself resolve.

In short we may now be said, in a military metaphor, to have "a force of all arms" at our disposal in the recognition, study, and treatment of disease.

What, amidst this profusion of resources, is now the place and importance of clinical observation by the trained senses, which at one time comprised virtually the entire activity of the physician? Has it been displaced? May we relegate it to the realm of the obsolete? Is its pursuit a mere archaism?

We are now in a period of unprecedentedly rapid growth in medicine, and it would be foolish, and contrary to history, to suppose that we are not even now exposed to all the dangers of partial thinking. Indeed, with the growth of our resources these dangers multiply, and I fear that the notion of clinical observation as a largely worked out method, as in some of its aspects an archaism, even more the notion that it has no secrets left to yield to its followers, have appeared amongst us and are in fact another manifestation of partial thinking.

I am suggesting to you the idea that perhaps the more balanced view is that for the clinician there is a hierarchy of methods at his disposal, and that, as in all hierarchies, one comes first and is indispensable.

The devastating epidemics of contagious diseases in the London of his day provided him with a rich material for study, and he succeeded in differentiating smallpox, cholera, plague, measles, scarlet fever, chorea, and that dignified malady of more spacious days, gout. His descriptions of smallpox and of gout are classics that can be read with profit today.

Sydenham gave a great impulse to clinical medicine throughout Europe, but his work was not based upon any systematic knowledge or study of morbid anatomy, and his successors of the 18th century degenerated into mere classifiers, adding nothing new but creating an arid discipline of cataloguing and subdividing symptoms. The ultimate aim of medicine could never be the mere development of nosography—that is the differentiation and naming of a morbid state and its reference to a descriptive category. Changes in bodily function and structure, and factors of causation of disease were also necessary subjects of study and of knowledge if power over disease was to be achieved. Clinical study could not advance indefinitely in a vacuum, as it were, and without a parallel study of anatomical and physiological factors.

The necessary impulse which started medicine off once more in the stream of progress came from France, where in the early 19th century Bichat and Corvisart developed a systematic pathological anatomy, and the clinicopathological method was born.

It is easy now, and in some quarters popular, to decry what is called "deadhouse pathology," "scorning the base degrees by which we did ascend," but its study was an imperative condition of progress in medicine, and it remains a step which we must still tread today.

Bichat advanced from the notion of diseased organs to that of diseased tissues. For example, he pointed out that the inflammation of a serous membrane gave rise to phenomena of two orders—those peculiar to all serous membranes, and those determined by the organ in which the serous membrane was situated and of which it was a part.

Thus, pleurisy, peritonitis, meningitis lead to general and to special or localising symptoms. Looked at today this notion of Bichat's seems an obvious and an easy one, and those who have never skirmished on the frontiers of ascertained knowledge in medicine, or any other branch of science, may not know how hard-won are these flashes of intuition, these fertile generalisations, how revealing when they are achieved, and how immensely satisfying to the earnest seeker after light in dark places. They come from what Trotter has spoken of as the unrelenting contemplation of the facts of observation—a contemplation we are apt to be far too busy nowadays to secure for ourselves.

Corvisart, following Bichat, undertook the precise study of pathological changes in tissues and organs and sought to correlate them with clinically observed disorders. This step made possible another one. Up to this time clinical observation had been essentially an ocular matter—the patient was looked at rather than systematically examined. For clinical examination as we know it, we owe the first steps to Laennec, who sought to discover in the living subject the changes in the organs hitherto seen only post mortem. His great weapon to this end was the method of auscultation by the stethoscope, and by means of it he was able to form some judgment of the actual changes present in heart and lungs.

I doubt if most of us now have the amazing skill with the stethoscope which the older physicians of my student days achieved, though I used sometimes to suspect that some of the ultimate refinements of auditory perception, with accounts of which some auscultatory artists used to regale us, were little imaginative. Perhaps it is no longer essential that we should possess this degree of artistry, for other methods have come to lend us, and to lend us more easily and more certainly, some of

the information gained by the stethoscope. But what the long bow was at Crecy, so was the stethoscope to our fathers in medicine, an essential weapon. Despite it not, nor suppose that the X ray film is the universal and adequate substitute for its use. A stethoscope can go into any man's pocket, but we can't trail an X ray plant and its operators round to every bedside.

Thus Laennec was able to construct a new series of clinicopathological pictures of disease, to distinguish the diverse pathological changes in the lungs, and in particular to form a unitary conception of pulmonary tuberculosis.

Those who followed him developed his methods, and gradually clinical medicine began to assume the form it still retains in essence, despite the vast accessions to knowledge that have ensued since his day.

From France, the new impulse spread. First, perhaps, to the Dublin school of medicine where Graves, Stokes, Adams, Cheyne, and Corrigan gave their names to new clinicopathological complexes, and thereafter to the country where Addison, Bright, Parkinson, and others added further clarifications and nosological additions to knowledge.

* * *

It is perhaps difficult for us now at this time to realise what a revolution these few fertilising geniuses achieved in a few years. Out of the formless welter of chronic illness, fresh clinicopathological entities were isolated so that all could identify them and know them in their clinical and pathological aspects.

Even yet, however, clinical medicine was obviously incomplete, and became threatened by a stagnation of the same order that followed the impulse originally imparted to it by Sydenham, and the tendency to think of disease complexes as static concrete entities began to show itself. What was missing was the notion of aetiology, and the notion of process. There was no awareness of the fact that structural change must be preceded by functional change, and that disorders of function presupposed normal function. The notion of disease as disorder of normal function was necessary to the further evolution of medicine.

The new impulse to the introduction of physiological ideas in medicine may be said to have come from Germany from the middle third of the last century onward. There it gained strength and effected yet another revolution in medicine. Even here, perhaps, the germinal idea came from France, and from the physiologist Magendie, who explicitly refused to accept a true distinction between physiology and pathology, and emphasised that post mortem findings of themselves could not account for all the clinically observed phenomena.

Nevertheless, it was really in Germany that physiological medicine, as its exponents proudly called it, came into its own. The study of disordered function and the interpretation of signs and symptoms in terms of function became the intense and fruitful study of men whose names are still familiar—Schwann, Remak, Henle, Traube, Virchow, Wunderlich, and others.

* * *

It would be difficult to overestimate the achievements of these men, and hard perhaps for some to appreciate the intellectual ferment in which they worked. Their aim was to penetrate deeper than the descriptive disciplines which were dominating medicine, and to understand the processes at work in disease.

To probe behind phenomena and to seek the principles they exemplify is the first step in a philosophy of medicine, for philosophy is the attempt to understand things by their causes.

Yet, as I have already observed, there is excess in all greatness, and once again the pendulum of opinion swung too far. The notion of process led inevitably to a distrust of the notion of specific diseases and their classification into groups, like animals or plants.

In a measure these German enthusiasts were right when they declined to accept a "disease" as a natural entity, as something in nature. In nature there are for the practising doctor only sick persons, and the composite average picture of disease we construct from the study of like illnesses in different persons is not something concrete, but simply a mental construct, and what the German physiological school was rejecting was what has been called "the fallacy of misplaced concreteness." Yet in exposing a logical error in current notions, they went too far when they denied the specific characters of many different illnesses which the insight of their predecessors had identified. In popular language they threw out the baby with the bath water—as enthusiastic reformers are so apt to do—and failed to realise that descriptions of different forms of illness, nosography, remains and must always remain essential to the clinician.

Nevertheless, this physiological epoch in the medicine of the 19th century, incomplete as were its insights, was a great, nay an essential, step in the forward growth of medicine, and it had the additional and priceless merit that it saw the introduction of the experimental method in medicine.

Yet, here also, history repeated itself, and once more an outlook that transformed the face of medicine came in a measure, and for a time, to distort perspective, as when Virchow, ignoring the art of medicine, proposed that practical medicine should become applied theoretical medicine. Under his influence, the strength of which it is now difficult for us to appreciate who have no towering figures in medicine comparable with the giants of 90 or 100 years ago, the clinical method and nosography in general became disparaged, its progress delayed and the art of medicine ignored. I sometimes think that even yet the clinician has not wholly regained that pride in his discipline which its exacting nature and its record of achievements demand, and is prone to accept too easily and to apply uncritically the facts he is offered from the experimental laboratory.

The same attitude towards the clinical method was shown by Claude Bernard in France when he invited the physician to desert the bedside for the laboratory in his search for knowledge, since he—as many lesser men since—believed the clinical method of study was worked out like an exhausted vein of precious metal in a mine.

Yet while Virchow and Bernard were writing obituaries of the clinical method, Charcot and Trousseau in France and Hughlings Jackson and others in this country were still demonstrating what the clinical method could achieve, not only in nosography, but also in the philosophic understanding of normal and disease processes. After all, the clinician is perhaps the best judge of the usefulness of his methods.

Trousseau, indeed it was, who made one of the first steps in the next essential condition of advance in medicine when he proposed "that what gives the specific diseases their immutable properties is not the quantity but the quality of the morbid cause" thus opening the stage of aetiological inquiry in medicine. To each particular cause of disease the system reacts with specific and characteristic phenomena. In other words when we endeavour to construct typical clinical pictures we are taking a first step to track down some specific pathological cause.

At the time of Trousseau's death in 1867, Pasteur was engaged upon brilliant studies of the cause of fermentation and putrefaction the fruit of which was to establish that many diseases were reactions to specific micro organisms, and bacteriology was born.

Neither time nor your patience would allow me to discourse upon the revolutionary influence of what has been called the germ theory of disease upon medicine.

My point rather is that this also, by its very success, tended to give a too exclusive outlook to the generation in which it developed and achieved its so striking triumphs.

Causation in disease was a larger and more complex problem than had yet been envisaged, and was the subject of a great deal of partial thinking—still current amongst us in those simple souls who like to see in chronic and obscure ill health the work of that nebulous concept "focal infection." A cynic has said that to "find a germ and stop thinking" is still the preoccupation of too many amongst us.

We have, in fact, forgotten Aristotle and his four orders of causation—material, formal, efficient, and final—and we are painfully relearning them in a terminology of our own, too often without realising that it is only a process of rediscovery.

In short, intemperate enthusiasms of doctrine still sway us, and perhaps never more than now when we see psychiatry and psychosomatic medicine running neck and neck, each seeking to become the master notion in modern medicine.

* * *

We have seen, then, in our time the progressive widening of our notions of causation, of aetiology, in disease. To bacteriology have been added insights derived from chemistry, biochemistry, and now physics and from the intermittent and often smoky light of psychology.

From all this mass of knowledge, a more philosophic notion of causation is taking shape, and has found expression with admirable lucidity and conciseness in a paper by Dr J. L. Halliday, entitled *Principles of Aetiology*, published in the *British Journal of Medical Psychology* in 1943. I could wish that this paper were far more widely known, for it is the best synthesis of a complex problem that I have met, and should be an admirable corrective to those recurrent accessions of dogmatic and partial thinking which, generation after generation, have disturbed the steady and rational process of growth in medicine.

A stage has now been reached when we realise that we have become increasingly dependent in medicine upon the application of biological and physical science to the solution of our problems. To take but a few obvious examples: the value of the X-ray film in the diagnosis of carcinoma of the lung, and its application of arteriography in the detection of intracranial aneurysm, and those blood and body fluid examinations of almost infinite diversity which are needed for the elucidation of problems that clinical observation raises but cannot by itself resolve.

In short we may now be said, in a military metaphor to have "a force of all arms" at our disposal in the recognition, study and treatment of disease.

What, amidst this profusion of resources, is now the place and importance of clinical observation by the trained senses, which at one time comprised virtually the entire activity of the physician? Has it been displaced? May we relegate it to the realm of the obsolete? Is its pursuit a mere archaism?

We are now in a period of unprecedentedly rapid growth in medicine, and it would be foolish, and contrary to history, to suppose that we are not even now exposed to all the dangers of partial thinking. Indeed, with the growth of our resources these dangers multiply, and I fear that the notion of clinical observation as a largely worked-out method, as in some of its aspects an archaism even more the notion that it has no secrets left to yield to its followers, have appeared amongst us and are in fact another manifestation of partial thinking.

I am suggesting to you the idea that perhaps the more balanced view is that for the clinician there is a hierarchy of methods at his disposal and that, as in all hierarchies, one comes first and is indispensable.

I am suggesting that for the good clinician the clinical method—the method of history-taking and direct examination—takes primacy, and that without it, and the lead it gives the prudent doctor, medicine becomes a chaos of activities and techniques, a blind fumbling after the truth in any particular case

It is the first clinical survey and judgment that determines what devices of applied science should be used and in what sequence, what special tests can be expected to yield a relevant answer and what cannot

All this clinical survey demands of us something over and above the skilled employment of applied scientific methods. It demands experience and prudence, or practical wisdom

In short, if I am right in my view, the clinical method of direct observation and examination has in it an element of practical wisdom, which the employment of scientific techniques of itself does not possess. It is relatively easy to acquire techniques, but judgment in their use is the reward of clinical experience carefully garnered. Judgment is of the essence of the clinical method in its fullness. It is easy to perform a lumbar puncture, but it is not so easy to know when and when not to perform it. It is simple to do an air ventriculogram, but apparently not so simple to know when to refrain from doing it—though indeed I have heard a surgeon say “it does nobody any harm to have air put into his ventricles”—naturally it was of someone else's ventricles that he was thinking when thus he spoke

I return now to my military metaphor, that in which I spoke of the clinician facing his tasks of diagnosis and treatment with a force of all arms at his disposal: clinical, chemical, biochemical, physical, bacteriological, pathological, radiological, and so on

Each such task that faces him is a different one, even the patient is no constant, but a sum of his inheritance, constitution and environment, and of the psychological influences that have helped to mould him. Therefore each task calls for generalship in the use of the available resources. Now a skilled general does not throw all his forces into every battle in an indiscriminate fashion. He chooses his weapons and the circumstances and the moment when he shall use them. In other words he uses judgment. His judgment may be fallible, the event may falsify it. Nevertheless, he remains aware that judgment, discrimination, and foresight are qualities expected of him and necessary to the maximal efficiency of his activities

So each of us needs to show generalship in the use of our resources, and this generalship requires as a condition of its possession by us, clinical observation and clinical judgment. And, further, this generalship, as I am calling it, is demanded of us not only because it is a logical use of reason, but also on grounds of prudence, that prudence that bids us cherish first of all the welfare of our patients

Now, you may say that it is never prudent to leave anything to chance, that more mistakes are made from carelessness than from ignorance. There is an element of truth in this, but it is not a justification for indiscriminate investigation, which is unintelligent, wasteful, and often a cause of discomfort and hazard to the patient. We still have the responsibility to plan systematically, to employ each test for an end we can both specify and justify, and to refrain from forms of investigation that can offer no relevant information and can promise no benefit to the patient

I suppose it would not be an exaggeration to say that every day many hundred square yards of X ray films are unnecessarily exposed and many man hours of radiographers' time—not to mention a deal of money—are squandered. Pathologists and bacteriologists could, I feel sure, echo my complaint on this score

I am not advocating a deliberate archaism of method, a refusal to be up to date, I am simply seeking to stress that the more resources we have the greater demand their use makes upon our intelligent forethought. They are demands upon clinical judgment and not substitutes for it

It will be time enough for us to reproach the State for the number of forms it requires the doctor to complete, when we have put some check upon our own private orgies of chit signing to the laboratory departments of our profession

* * *

It seems to me, therefore, that there are two lessons we may learn from the history of modern medicine, lessons for the teacher not less than for the taught. That the clinical discipline is the real and only sound foundation of wisdom in the practice of medicine. Secondly, that a great safeguard against partial thinking and specialist enthusiasms is, at least for those who teach medicine, some measure of understanding of the history of modern medicine. This does not simply mean familiarity with the chronicles of medicine, which is what is commonly understood by the term “the history of medicine”. After all, chronicles are merely the raw material of history. What we need is some appreciation of the movements of thought, the rise of new insights—their good and their bad influence. Modern medicine is rooted in its past, and of that past we should seek to understand the significance. Such an understanding is surely vital to the teaching of medicine. Only when we possess it can we hope to orient ourselves in the rapidly growing body of knowledge and avoid the errors and illusions of finality of our predecessors and of some of our contemporaries

The one enduring and unbroken thread which runs through the past three centuries of medical history, sometimes hidden in the rich and intricate fabric of medical knowledge, but always holding it together and lending coherence to its pattern, is the clinical discipline. Without it, medicine must become a chaos of techniques employed by clever people devoid of humanism and practical wisdom

ADJUVANTS TO STREPTOMYCIN IN TREATING TUBERCULOUS MENINGITIS IN CHILDREN

I A B CATHIE
M.D. Lond

J C W MACFARLANE
M.D. B.Sc. Glasg

CLINICAL PATHOLOGIST

ASSISTANT CLINICAL PATHOLOGIST

THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET,
LONDON

OUR purpose is to amplify the preliminary communication of one of us (Cathie 1949b) on the use of streptolysase as an adjuvant to streptomycin in the treatment of tuberculous meningitis, and to compare the results with those of other treatment centres

From February, 1947, when streptomycin became available for the treatment of tuberculous meningitis under the auspices of the Medical Research Council's trial (first 14 cases), until November, 1949, 60 cases have been admitted to the Hospital for Sick Children for treatment (table 1). The first 20 (series A) were treated with streptomycin alone, and 5 (25%) of these are at present alive, of whom 4 have normal cerebrospinal fluid (C.S.F.)

This survival rate of 25% which accords with many other comparable published figures, was a great disappointment to us, and we felt that, although streptomycin could cure some of the cases (which no drug hitherto had been able to do) some other form of adjuvant therapy must be included if the survival rate was to be improved.

We report here the results in 40 patients (series B), of whom 23 (58%) have survived, 17 with normal C.S.F., and discuss the adjuvant forms of therapy which have been used and which may have contributed to the improved survival rate

MATERIAL

Except for 2 cases which were treated independently and were not available to us, the cases in our two series were consecutive hospital admissions, and none has been excluded because of the severity of the condition or the

shortness of the period of treatment Table II shows that the series are comparable as regards age, severity, and presence or absence of military tuberculosis, as was to be expected when the children were consecutive admissions

All the cases were proved bacteriologically, and all the patients were Mantoux positive The youngest child was aged 4 months, and the oldest 12 years Since the last admission in series B was in November, 1949, all the patients referred to were under observation

TABLE I—ANALYSIS OF CASES

Case no	Age on admission (years)	Severity	Miliary tuberculosis present or absent	C.S.F.		Signs of raised intracranial pressure	Treatment				Length of observation since admission (weeks)	Results	
				Film	Culture		Intraventricular drainage	No. of 6 week courses	Sulphathione	Streptomycin		Weeks with normal C.S.F.	Final state
1	2 1/2	S	-	+	+	+	-	-	-	-	25	102	Died
2	4 1/2	S	+	+	+	+	-	-	-	-	3

* Cases developing meningitis while on treatment for military tuberculosis

† The period is italicized where some abnormality remained. Cases 25 and 32 developed spinal caries after 80 and 9 weeks respectively in which their C.S.F. was normal, and in neither case has there been relapse of meningitis Case 38 developed tuberculous arthritis of the knee after 12 weeks with normal C.S.F. without meningeal relapse

TABLE II—HOMOGENICITY OF SERIES A AND B AS REGARDS AGE, SEVERITY OF ILLNESS, AND PRESENCE OF MILIARY TUBERCULOSIS

Series	Age (yr)		Miliary tuberculosis		Severity of illness on admission		
	Below 3	Above 3	Present	Absent	Early	Moderate	Severe
A (20 cases)	11 (55%)	9 (45%)	5 (25%)	15 (75%)	5 (25%)	9 (45%)	6 (30%)
B (40 cases)	18 (45%)	22 (55%)	13 (33%)	27 (67%)	11 (27%)	21 (53%)	8 (20%)

for at least six months and so, if they survived, received our standard six months' intramuscular treatment

BACTERIOLOGY

Of our 60 cases 1 was treated partly at another hospital, where *Mycobacterium tuberculosis* was seen but cultures were not made. This leaves us with 59 cases. In 58 (97%) of these the *Mycobacterium tuberculosis* was grown on culture, in the other it was grown from guinea-pig inoculation. From the beginning the routine was to wait for a fortnight for cultures to become positive on Lowenstein-Jensen's medium, if at the end of this time there was no apparent growth, guinea-pigs were inoculated with the pooled sediment remaining from routine lumbar punctures. This was necessary three times, although in two of these cases the initial cultures became positive after it had been thought necessary to inoculate a guinea-pig. With such a high rate of positive cultures there was no reason to alter this routine, which proved very economical of guinea-pigs.

Of the 59 patients seen from the start of their illness *Mycobacterium tuberculosis* was found on direct examination of the C.S.F. in 52 (88%). The determining factor in this high rate of positive films seems to have been their method of preparation: after centrifugation the part of the sediment to be examined was deposited in pinhead drops on the slide. By this means it was possible to examine the whole deposit rather than the small portion which is examined when such a drop is smeared.

From the 59 cases the initial culture was sensitive to streptomycin, the greatest concentration necessary to inhibit growth being 0.5 µg per ml. No organism was more than twice as resistant as the standard strain of *Mycobacterium tuberculosis*, H37Rv (cf. Medical Research Council 1948).

Every specimen of C.S.F. was cultured as a routine. In addition, where possible, necropsy samples were cultured. Five strains completely resistant to 2000 µg of streptomycin per ml were recovered from the 32 patients who died, giving an incidence of 8.3% in our 60 cases. This does not agree with other workers' findings and may possibly be due to the routine culturing of all C.S.F. samples.

All our patients were Mantoux positive, and treatment was not instituted in the face of a negative reaction except in 1 child who proved to have a cerebellar tumour. Where practicable we have proceeded straight to a strength of 1/100. We have seen no reaction, local or general, of such violence that we have regretted it, and it avoids the occasional loss of forty-eight hours while waiting for a 1/1000 test to prove negative.

CEREBROSPINAL FLUID

Normal—We regard normal C.S.F. as having at least 45 mg of sugar per 100 ml, 40 mg or less of protein per 100 ml, and 4 or fewer cells per cmm. We have adhered rigidly to these criteria in calling a C.S.F. normal.

Abnormal—We have nothing to add to the findings of the Medical Research Council (1948) or those of Rubie and Mohun (1949), MacCarthy and Mann (1950), and others. The C.S.F. chloride level gave us little help. The C.S.F. glucose level was the most consistent aid in

diagnosis and prognosis, and indicator of recrudescence. The shortest time in which the C.S.F. returned to normal was twelve weeks (case 25). On the other hand, case 19 has been off all treatment for two years and back at school for one and a half, yet, with a normal chemistry for a year, his C.S.F. still has 14 cells per cmm, with no tendency for them to diminish. Although as the result of the treatment he may have established now normal for himself, we cannot by our criteria call him a complete recovery.

METHODS

The first 14 cases of series A were treated with continuous intramuscular streptomycin for six months and periods of a month's daily intrathecal streptomycin by the lumbar route with intervening rests. The dosage was that recommended by the Medical Research Council (1948). In the last 6 cases of series A the number of intrathecal injections was gradually reduced. Series B was treated with the same dosage of intramuscular streptomycin for six months, and the intrathecal course aimed at was daily for a fortnight, every other day for a fortnight and every third day for a fortnight, making a total of twenty-four intrathecal injections. At the end of such a course intrathecal therapy was stopped to see what would happen in the C.S.F. If the C.S.F. showed signs of improvement, no further intrathecal treatment was given, but, if there was any sign of deterioration, a further six-week course was given. Particular attention was paid to the C.S.F. glucose level.

'Sulphathione' and streptokinase were added to the streptomycin with each intrathecal injection in series B, except for 6 who received no sulphathione. The dose of sulphathione was 0.05 g for children under the age of 3 years and 0.1 g for older children. Streptokinase was given in doses of 0.5 and 1 ml respectively to these age groups, the titre of the preparation being about 1/600 (Cathie 1949a).

Ventricular drainage was used in series B whenever it was considered necessary.

SULPHATHIONE

After a visit to Prof C. Cocchi's clinic in Florence in 1947, where we were impressed by his results with streptomycin and sulphone, we decided to incorporate a sulphone in our treatment. At that time sulphathione seemed to be the least toxic (Brownlee et al. 1948a and b), so we chose that. We soon found that to obtain C.S.F. levels of 1.5 mg per 100 ml with oral or intramuscular sulphathione we had to give toxic doses. Since such levels were roughly only a hundredth of the bacteriostatic level for *Mycobacterium tuberculosis*, we decided to give intrathecal sulphathione in doses of 0.05 or 0.1 g. This seemed to have little irritant effect on the meninges and mixed readily with streptomycin. Unfortunately 50% of the sulphathione so given was excreted within six hours, and at twenty-four hours only 2–5 mg per 100 ml remained. Since, however, sulphathione was thought to have a synergistic action with streptomycin it was given in 34 cases.

After 19 cases had been treated with streptomycin, streptokinase, and sulphathione, and it had become clear that the results were improving considerably, sulphathione was omitted from the next 6 cases so that the part played by it could be assessed. We then felt it desirable to reintroduce the sulphathione for the remaining 15 cases of series B while the 6 who did not receive it were being observed. Of the 34 treated with sulphathione 19 (56%) are alive. Of the 6 who did not receive it 4 survived. Although the numbers are too small to be of much value they confirm an impression that sulphathione plays little part in recovery from tuberculous meningitis, and we are not using it any longer. In this conclusion we are supported by that of the Veterans' Administration (1949), whose streptomycin results were not improved

in 43 cases in which 'Promizole' was used as the sulphone adjuvant. Before a final opinion can be reached on the value of a sulphone the results of Professor Cocchi (see below) and those of Lincoln and Kirmse (1949) must be considered. Lincoln and Kirmse reported that 13 out of 18 cases appeared to be doing well 3-6 months after treatment had started with promizole as an adjuvant, and a follow up of these cases is awaited with interest.

STREPTOKINASE

In the search for some adjuvant which would promote lysis of the fibrinous exudate in tuberculous meningitis we turned to streptococcal fibrinolysin, or streptokinase (Cathie 1949a), and a preliminary report of its apparent efficacy was published (Cathie 1949b). Briefly, it was found that streptokinase could *in vitro* lyse fibrinous exudate taken from the base of the brain post mortem. Streptokinase has also unblocked an internal hydrocephalus in a *Haemophilus influenzae* meningitis and, when given alone, has caused tubercle bacilli to reappear in the C.S.F. in cases where treatment had been abandoned.

Streptokinase was standardised on fibrin clots prepared from plasma which were comparable to the spider's web clots of C.S.F. in cases of tuberculous meningitis. Assuming that a hundredfold dilution occurred when 1 ml was injected intrathecally, a preparation was used whose potency was such that a dilution of 1/600 could lyse our standard clot in an hour. By our method of preparation streptokinase was miscible without deposit only with the calcium free salts of streptomycin. When given alone intrathecally it caused a pleocytosis similar to that seen with streptomycin, with some small increase

Incidence of signs of raised intracranial pressure (hatched columns) and intracranial pressure (stippled columns) in series A and B

later in 12. In series B, all of whom had streptokinase, similar signs were present in only 25 cases out of 40, coming on in the first fortnight of treatment in 20 cases and later in 5. It seems reasonable to suppose that streptokinase, if it can affect the exudate, would take some time for its effect to become manifest. We have therefore considered indications for intraventricular catheterisation arising within the first fortnight and subsequently after the start of treatment. In series A, without streptokinase, these indications were seen later in 12 out of 20 cases (60%). After the introduction of streptokinase, in only 5 cases out of 40 (12%) was catheterisation considered necessary after the first fortnight. The accompanying figure shows the percentages of those patients at risk who developed signs of raised intracranial pressure in series A and B in the first fortnight and subsequently.

Case 37 was atypical in that he presented with signs of a block in the dorsal region, confirmed by a myelogram. Tubercle bacilli and a protein content of 3400 mg per 100 ml were found in the lumbar C.S.F., whereas C.S.F. obtained by cisternal puncture was almost normal. 1 ml of 1% methylene blue injected into the ventricle did not stain the lumbar

C.S.F. The patient was treated with streptokinase alone for a month, 1 ml on alternate days by the ventricular and lumbar routes. Methylene blue was first detected in the lumbar C.S.F. after ventricular injection at the end of three weeks. The patient was next treated with intrathecal streptomycin, and made an excellent clinical recovery, but the lumbar C.S.F. still contains 200 mg of protein per 100 ml. after ninety eight weeks observation.

VENTRICULAR DRAINAGE

In considering series A we were bound, like other workers, to be struck by the overwhelming incidence of hydrocephalus, both at necropsy and as demonstrated by air encephalography in the survivors. So near was this incidence to 100% that it seemed reasonable to institute ventricular drainage at the start of treatment as a prophylactic measure. Yet some patients recovering with hydrocephalus appeared entirely normal, hence catheterisation was reserved for those cases in which we felt that there was a clear indication that relief of intracranial pressure would alleviate the symptoms.

The indications for ventricular drainage and their incidence were as follows:

Indication	No of cases	% of total
Coma, or increasing drowsiness	27	62
Papilloedema or blurring of optic disc	29	66
Intractable vomiting	27	62
Fits	16	36
Changes in the lumbar flow of C.S.F.	14	31
Generalised spasm	10	23

Though any single one of these indications would have warranted catheterisation, with the exception of blurred discs they seldom occurred singly. In a few cases a rapid general deterioration in the patient's state without particular symptoms led us to insert catheters, and in every such case the intracranial pressure was found to be greatly increased.

At first intraventricular catheterisation was regarded as a major operation, and secondary sepsis was feared. We are now less frightened of sepsis, catheterisation is usually done by the resident surgeon, and for ease of nursing and the comfort of the patient an anterior approach to the lateral ventricle is chosen. In infants with the fontanelle still open direct needling of the lateral ventricle is easily done, and there is consequently no need for catheterisation.

An advantage of catheters, apart from the relief of pressure, is that therapy can be given by the ventricular route, and thus rest can be given to the lumbar area as well as the patient, moreover, in those infrequent cases where the hydrocephalus is internal there might theoretically be an advantage in attacking the exudate from above. Also, whereas release of excess C.S.F. via the lumbar route may predispose to coning of the cerebellum into the foramen magnum, ventricular drainage should tend to prevent this.

RECRUDESCENCE AND RELAPSE IN RELATION TO 6 WEEKS' INTRATHECAL TREATMENT

In our early cases we had felt that perhaps we were overtreating by the intrathecal route, particularly in view of the known toxic effects of streptomycin. Therefore in the last 6 cases of series A the number of intrathecal injections was progressively reduced, because it was thought that we were not likely to obtain worse results than 2 survivors out of 14. The clinical response in 3 of these 6 was sufficiently encouraging for us to decide to aim at a six week course in series B. Actually these 3 survived.

Only 1 of our patients (case 21) has shown a true relapse, which came on three months after the C.S.F. had become normal. An attack of measles after the child had apparently recovered may have contributed to this, although the child was admitted and treated with intramuscular streptomycin during the illness. In 5 other children, who showed excellent clinical improve

ment and a C S F returning to normal, there was a relatively sudden deterioration in the C S F followed by clinical relapse. They all died, and in each case the tubercle bacillus was later shown to have become completely streptomycin resistant. 2 of these cases were in series A: one had had continuous intrathecal treatment until death, and the other had had an eleven week intrathecal course. The 3 other cases, in series B, had had the six week intrathecal course.

Three of series B (cases 31, 41, and 50) were given a second six week course because, although the clinical condition was good, the C S F sugar level was not considered satisfactory, they all survived. 3 children (cases 36, 48, and 54) had a second intrathecal course because the C S F did not improve after the end of the first and the clinical condition had deteriorated concomitantly, they all died. In case 24, after completion of intrathecal and 6 months' intramuscular streptomycin therapy the C S F remained abnormal. After six weeks tubercle bacilli reappeared, and the patient was given another six months' intramuscular streptomycin and two six week intrathecal courses with apparent recovery. The C S F in this child has now been normal for four months.

With our rigid criteria of C S F normality, only case 21 can be called a true relapse, and the others, in some of whom the C S F was approaching normal, are regarded as recrudescences. For this reason we are chary of mentioning cases "doing well," and little is yet known of the prognostic significance of a C S F that remains abnormal.

In series B, besides the 3 cases with streptomycin resistant tubercle bacilli, the 3 who died in spite of further treatment, and the 1 who died in relapse, there were 10 who after six weeks were either dead or in such a hopeless state that treatment was abandoned. These 10 would have had the same outcome whatever the intrathecal course of streptomycin. Thus there were 23 cases out of 40 who recovered with the six week intrathecal schedule: 19 after a single course, 3 after a second six week course, and 1 after six months' treatment. We are well aware that the adjuvant therapy played a part in the recovery rate, but the figures show clearly that as good survival rates may be obtained

with 24 intrathecal injections as by treating with intrathecal streptomycin for much longer periods or until a normal C S F is attained.

Of the 3 strains of streptomycin resistant tubercle bacilli 2 were grown in the twelfth, and 1 in the fifteenth, week of illness, in each case after many weeks of sterile cultures. In no case was developing resistance seen, adjacent positive cultures being sensitive and totally resistant. We do not know whether longer or shorter periods of intrathecal treatment than six weeks would avoid this catastrophe, nor have we sufficient cases to answer the question, but, following the Medical Research Council's (1949) report we have added *p* aminosalicylic acid (given by mouth) to the battery of drugs in the hope that the number of resistant strains will diminish.

OTHER RESULTS

The results published from other treatment centres which have had large enough series of cases are summarised in table III. Much of the information is obviously unsatisfactory. In some instances the cases were selected because of their likely response to streptomycin therapy, in others meningitis with miliary spread was excluded, and in some there is doubt whether the cases were proved or not.

There is little information about the final state of the C S F. Since some of the patients were still under treatment, this is not surprising, but, since the persistence of abnormality in the C S F may be of prognostic significance, we have felt that it is essential for the C S F to be normal before a case can be regarded as a recovery.

Table III shows that Professor Cocchi (reported by Pasquinucci 1949) divided his cases into three series: all treated with sulphone and different schemes of streptomycin dosage. We do not know how well the third series has done, because at the time of publication many patients were still under treatment, but the second series, with 47% survivors and 42% with normal C S F out of 60 unselected proved cases, bears favourable comparison with anything yet published. Since the first series of 57 cases, with 23% survivors and 14% with normal C S F, was, like the second series, also treated with sulphone as an adjuvant, the variation being in streptomycin dosage, we feel that the greatly improved results point to the streptomycin dosage rather than to the sulphone as the responsible factor.

Cocchi (1949) thinks combined treatment with streptomycin and sulphone makes for less frequent development of streptomycin resistance in the tubercle bacilli, as has been suggested for that with streptomycin and *p* amino salicylic acid. Our results with sulphathione do not answer this question either way.

In his third series it is noteworthy that Cocchi is using intraventricular catheterisation, and he is optimistic about the ultimate results. The other treatment is as in the second series.

DISCUSSION

The results we have obtained with the scheme of treatment outlined do not suffer by comparison with any others. In attempting to evaluate the adjuvants which have increased the survival rate we are bound to be perplexed by their number and the difficulty in assigning a part to each. We are not at present in a position to pass final judgment on sulphathione, although our impression that it is not of great value finds support in the experience of other workers and possibly from Cocchi's results.

We are convinced that ventricular drainage is a life saving measure in acute hydrocephalus and should be resorted to wherever there are indications of a raised intracranial pressure. But this measure is entirely asymptomatic, and can have no effect upon the tuberculous process.

Series B					

It is our view that streptokinase has been the most important single factor in the improvement in the second series of cases. By its effect it may predispose to earlier healing, but its major effect has been in the reduction in the number of cases which developed signs of a raised intracranial pressure (19 out of 20 in series A, against 25 out of 40 in series B). The indications of its positive, rather than prophylactic, value have already been pointed out. Judging by the requests we have received for streptokinase for cases of established hydrocephalus, there seems to be some misconception of the part it can play. While in our experiments we have found streptokinase to be capable of lysing gelatinous exudate it has no effect on fibrous tissue at all, and to try and lyse the organising exudate usually present by the time hydrocephalus has appeared with a fibrin lysis is to attempt the impossible. Thus streptokinase must be given from the commencement of treatment if its full effect is to be obtained, and we have found it is of no value late in the disease.

The last point in favour of the scheme of treatment outlined is that our results have been achieved with, on the average 24 intrathecal injections. This clearly holds advantages over the present tendency to treat intrathecally until a normal C.S.F. is achieved, particularly if the time necessary to attain such a result is considered from the patient's point of view.

Finally, we feel that no patient can be treated by a hard and fast scheme or rhythm of injections. Cases of tuberculous meningitis differ so widely from one another that every case should be treated with some régime that will permit of almost indefinite variation.

SUMMARY

The results obtained in two comparable series of tuberculous meningitis are presented.

In a series of 20 cases treated with streptomycin alone there were 6 (25%) survivors, 4 with normal C.S.F.

In a series of 40 cases treated with streptomycin, streptokinase most of them with sulphathione and intraventricular drainage where indicated, there were 23 (58%) survivors, 17 with normal C.S.F.

The part played by the adjuvants used in the series of 40 cases is discussed.

The results obtained by other treatment centres are summarised.

We are greatly indebted to the physicians of The Hospital for Sick Children, under whose care the cases were and particularly to Prof A. A. Moncrieff for his constant interest. Thanks are also due to the nurses, on whose shoulders the burden of treatment has fallen, and to our surgical colleagues for help with the catheters.

TREATMENT OF ACUTE BARBITURATE POISONING

A COMPARISON OF NIKETHAMIDE AND AMPHETAMINE*

JOHN RIISHEDE

ASSISTANT PHYSICIAN, MUNICIPAL HOSPITAL, AARHUS, DENMARK

From the University Medical Clinic of the Hospital

EARLIER investigations of barbiturate poisoning have proved the importance of active therapy aimed partly at removal of the ingested poison from the body and partly at maintaining the fluid salt balance and the circulation. It is only during recent years that these conditions have been fully understood, and the clinician has only lately appreciated the necessity for frequent assessment of the state of the circulatory and the fluid salt balance.

The object of the present study was to compare the value of nikethamide and of amphetamine as cerebral and circulatory stimulants in the treatment of acute barbiturate poisoning. A total of 193 patients with barbiturate poisoning were treated on exactly the same principles, except that in the first 61 cases nikethamide was used as a stimulant and in the subsequent 132 cases amphetamine. The mortality in the amphetamine series was only a fifth of that in the nikethamide series, moreover, the cases in the amphetamine series had an obviously less eventful course, with fewer complications.

MATERIAL

The material comprises the cases of acute barbiturate poisoning admitted to the University Medical Clinic in Aarhus from Nov. 1, 1946, to June 1, 1949. Slight cases in which stimulation was not required, or in which only prophylactic stimulation was used, are not included.

TREATMENT

In all the cases, without exception, the treatment was as follows:

(1) Aspiration of the stomach and gastric lavage with 10 g of medicinal charcoal in 250 ml of water, followed by instillation of 30 g of medicinal charcoal and 15 g of magnesium sulphate in about 500 ml of water.

In patients who on admission were comatose or later lost consciousness the following measures were taken:

- (2) Stimulation with nikethamide or with amphetamine.
- (3) Stimulation of peristalsis with neostigmine 1 mg four hourly till carbon had been evacuated per rectum or the patient was awake.
- (4) Prophylactic measures against pneumonia with sulphonamides or penicillin, or both.
- (5) Parenteral administration of at least 2-3 litres of fluid per twenty-four hours to maintain the fluid balance.

Every comatose patient was placed in bed with his head low, and mucus was aspirated from the larynx as long as the comatose and semicomatose state lasted; this was done with an ordinary water suction pump. If necessary, mucus was removed from the trachea and bronchi by bronchoscopy. The pulse-rate and temperature were recorded every hour, and the blood-pressure and hæmoglobin percentage every second hour. A catheter was passed twice every twenty-four hours, and serum protein, serum-chloride, serum bicarbonate, and blood urea levels were determined once every twenty-four hours. If the hæmoglobin percentage increased more than 10% ("imminent shock"), or if signs of manifest shock were found a blood transfusion was given—generally 1 litre at a time. Pulmonary oedema was treated by intravenous strophanthin (0.25 mg) and 50% solution of glucose (100 ml), in one case

* A Danish version of this paper was published in *Ugeskrift for Læger* 1950 112, 507.

ment and a C.S.F. returning to normal, there was a relatively sudden deterioration in the C.S.F. followed by clinical relapse. They all died, and in each case the tubercle bacillus was later shown to have become completely streptomycin resistant. 2 of these cases were in series A: one had had continuous intrathecal treatment until death, and the other had had an eleven week intrathecal course. The 3 other cases, in series B, had had the six week intrathecal course.

Three of series B (cases 31, 41, and 50) were given a second six week course because, although the clinical condition was good, the C.S.F.-sugar level was not considered satisfactory, they all survived. 3 children (cases 36, 48, and 54) had a second intrathecal course because the C.S.F. did not improve after the end of the first and the clinical condition had deteriorated concomitantly, they all died. In case 24, after completion of intrathecal and 6 months' intramuscular streptomycin therapy the C.S.F. remained abnormal. After six weeks tubercle bacilli reappeared, and the patient was given another six months' intramuscular streptomycin and two six week intrathecal courses with apparent recovery. The C.S.F. in this child has now been normal for four months.

With our rigid criteria of C.S.F. normality, only case 21 can be called a true relapse, and the others, in some of whom the C.S.F. was approaching normal, are regarded as recrudescences. For this reason we are chary of mentioning cases "doing well," and little is yet known of the prognostic significance of a C.S.F. that remains abnormal.

In series B, besides the 3 cases with streptomycin-resistant tubercle bacilli, the 3 who died in spite of further treatment, and the 1 who died in relapse, there were 10 who after six weeks were either dead or in such a hopeless state that treatment was abandoned. These 10 would have had the same outcome whatever the intrathecal course of streptomycin. Thus there were 23 cases out of 40 who recovered with the six week intrathecal schedule. 19 after a single course, 3 after a second six-week course, and 1 after six months' treatment. We are well aware that the adjuvant therapy played a part in the recovery-rate, but the figures show clearly that as good survival rates may be obtained

with 24 intrathecal injections as by treating with intrathecal streptomycin for much longer periods or until a normal C.S.F. is attained.

Of the 3 strains of streptomycin resistant tubercle bacilli 2 were grown in the twelfth, and 1 in the fifteenth, week of illness, in each case after many weeks of sterile cultures. In no case was developing resistance seen, adjacent positive cultures being sensitive and totally resistant. We do not know whether longer or shorter periods of intrathecal treatment than six weeks would avoid this catastrophe, nor have we sufficient cases to answer the question, but, following the Medical Research Council's (1949) report we have added *p* aminosalicylic acid (given by mouth) to the battery of drugs in the hope that the number of resistant strains will diminish.

OTHER RESULTS

The results published from other treatment centres which have had large enough series of cases are summarised in table III. Much of the information is obviously unsatisfactory. In some instances the cases were selected because of their likely response to streptomycin therapy, in others meningitis with miliary spread was excluded, and in some there is doubt whether the cases were proved or not.

There is little information about the final state of the C.S.F. Since some of the patients were still under treatment, this is not surprising, but, since the persistence of abnormality in the C.S.F. may be of prognostic significance, we have felt that it is essential for the C.S.F. to be normal before a case can be regarded as a recovery.

Table III shows that Professor Cocchi (reported by Pasquinucci 1949) divided his cases into three series, all treated with sulphone and different schemes of streptomycin dosage. We do not know how well the third series has done, because at the time of publication many patients were still under treatment, but the second series, with 47% survivors and 42% with normal C.S.F. out of 66 unselected proved cases, bears favourable comparison with anything yet published. Since the first series of 57 cases, with 23% survivors and 14% with normal C.S.F., was, like the second series, also treated with sulphone as an adjuvant, the variation being in streptomycin dosage, we feel that the greatly improved results point to the streptomycin dosage rather than to the sulphone as the responsible factor.

Cocchi (1949) thinks combined treatment with streptomycin and sulphone makes for less frequent development of streptomycin resistance in the tubercle bacilli, as has been suggested for that with streptomycin and *p* aminosalicylic acid. Our results with sulphathione do not answer this question either way.

In his third series it is noteworthy that Cocchi is using intraventricular catheterisation, and he is optimistic about the ultimate results. The other treatment is as in the second series.

DISCUSSION

The results we have obtained with the scheme of treatment outlined do not suffer by comparison with any others. In attempting to evaluate the advantages which have increased the survival rate we are bound to be perplexed by their number and the difficulty in assigning a part to each. We are not at present in a position to pass final judgment on sulphathione, although our impression that it is not of great value finds support in the experience of other workers and possibly from Cocchi's results.

We are convinced that ventricular drainage is a life saving measure in acute hydrocephalus and should be resorted to wherever there are indications of a raised intracranial pressure. But this measure is entirely symptomatic, and can have no effect upon the tuberculous process.

TABLE III—FIFTY FOUR SEVERE CASES IN AMPHETAMINE SERIES DISTRIBUTED ACCORDING TO HIGHEST BLOOD PRESSURE COMPARED WITH AVERAGE DOSE OF AMPHETAMINE IN CORRESPONDING GROUPS FIGURES IN PARENTHESES SHOW SMALLEST AND LARGEST DOSES GIVEN IN RESPECTIVE GROUPS

Highest systolic blood pressure (mm Hg)	No. of cases	Dose of amphetamine (mg) average min and max.
100-150	22	1026 (50-4000)
150-175	20	1906 (75-4850)
175-200	9	1843 (100-2825)
200-250	3	1762 (1340-2075)

Case 2—A woman, aged 35, was admitted after having taken an unknown amount of some soporific at an unknown time. She was deeply comatose and did not respond to pain. She was cold and sweating with imperceptible pulse and unmeasurable blood pressure. After treatment with amphetamine for twenty hours (total dose 1075 mg) she woke up and had no discomfort attributable to the therapy.

As a curiosity it may be mentioned that a pregnant woman at full term, who was admitted with severe poisoning with allyl isopropyl barbituric acid, was delivered of a completely normal child during the treatment. She did not wake up until four hours after the delivery. By that time she had been treated with amphetamine for thirty two hours (total dose 1525 mg) and owing to circulatory shock she had received a blood transfusion.

Side effects (table I) were seen in 28% of the patients treated with amphetamine, but in all cases they were slight and only transitory. Thus, vomiting occurred in only 7% of the severe cases as compared with 42% in the nikethamide series, and most of the patients vomited only once. As is indicated in table II, side-effects were much less frequent than in the nikethamide series.

In 13 patients electrocardiography was done after the treatment—in 9 within the first twenty-four hours after treatment had been discontinued. The electrocardiograms in 11 cases, including that of a patient who had received 4850 mg of amphetamine, were normal. One patient had low T_1 and T_2 and inverted T_3 waves, though the electrocardiogram had been normal two years previously. This patient, aged 45, was a chronic addict to alcohol and had had delirium tremens twice during the past two years, and it is unlikely that the changes were due to the amphetamine. The remaining patient was known to have heart disease with bundle-branch block, and the electrocardiogram was unchanged after the amphetamine treatment.

The effect of amphetamine on the blood pressure is difficult to assess, because the blood pressure is also affected by several other factors in the treatment. If, arbitrarily, it is assumed that rises of the systolic blood-pressure above 150 mm Hg are produced by amphetamine, more than half of the severe cases had a rise in the blood-pressure of this kind (table III). Table III also shows that there is no definite relation between the dose of amphetamine and the greatest height of blood-pressure reached.

The blood-pressure remained high for one or two hours, and then fell spontaneously to more moderate levels. In no case was it thought necessary to withdraw amphetamine because of raised blood-pressure. In 2 cases amphetamine 100 mg per hour was given for three and twelve hours without any change in blood pressure. In 1 of them extrasystoles and slight tremor were observed, but these symptoms subsided as soon as the dose was reduced to the usual 50 mg per hour, the other patient had no discomfort whatever from the treatment. The patient with bundle branch block had for several years had a blood pressure of about 220/150 mm Hg. He was aged 60, and in four hours he received 250 mg

of amphetamine. During the treatment the blood-pressure fell from 220/150 to 170/105.

The figures for slight cases of poisoning do not allow any definite conclusions about changes of blood pressure, but they point in the same direction as those mentioned above.

It thus seems that the effect of amphetamine on the blood pressure does not restrict its use in the treatment of acute barbiturate poisoning. Pre-existing hypertension is no contra-indication.

DISCUSSION

In the two series the age-distribution is uniform and the information obtained about the type and amounts of the hypnotics and the time of their ingestion does not differ materially. In the amphetamine series only 44% of the intoxications were "severe" cases, compared with 70% in the nikethamide series, but, according to the definition, assessment of severity depends on the efficacy of the therapy, and it is highly probable that this difference between the two series is due to the pronounced "exciting" effect of amphetamine. In the nikethamide series several patients who were awake became unconscious during the treatment, and according to the definition they were then placed under the heading "severe cases," whereas this happened in only 1 case among those treated with amphetamine.

As previously stated, apart from the stimulant used the treatment was essentially the same in the two series. The change from sulphonamides to penicillin cannot have altered the mortality, since none of the patients had massive or extensive pneumonia, and in only 1 case can bronchopneumonia (found at necropsy) be interpreted as the cause of death.

Blood transfusion was given in 33% of the severe cases in the amphetamine series, compared with 16% in the nikethamide series. The indications for transfusion were the same throughout the entire period. The difference must therefore be taken as an expression of the greater efficacy of amphetamine therapy, because the frequency of the presence of these indications will increase with the time of survival of severely poisoned patients. It has already been mentioned that the patients treated with nikethamide were more often in a more critical condition than those treated with amphetamine when the shock appeared. In the nikethamide series all 7 patients who were given blood-transfusions died, whereas in the amphetamine series 12 survived out of the 19 thus treated.

In both series moderate deviations from normal of the serum chloride, serum bicarbonate, and blood-urea levels were seen in patients who were unconscious for long periods, but these deviations could be compensated by the daily administration of fluid without special measures being taken.

The temperature was alike in the two series. It was high in most severe cases and showed a tendency to increase with the duration of the coma. Antipyretics were of no avail, whereas direct cooling was often of use in reducing the temperature.

The neostigmine treatment cannot be said to have abolished the paralysing effect of the barbiturates on the intestines, but in several cases, even in deeply comatose patients, a rapid action of neostigmine was seen, as shown by rectal evacuation of carbon about an hour after the first injection of the drug. The effect seems to have been best in the nikethamide series, presumably because amphetamine to some extent inhibits peristalsis.

There seems to be no reason for questioning the uniformity and comparability of the two series, and the improved results obtained by the change from nikethamide to amphetamine—a decrease of the mortality figure from 44% to 9%—must therefore be considered significant.

venesection was done. If cyanosis was present, oxygen was given.

During the first ten months, nikethamide was used as stimulant (Strömberg 1943). A 25% solution was used, 10 ml intravenously and 10–15 ml intramuscularly were given at once, and then 5–20 ml an hour was injected, according to the patient's response. Sulphonamides were used prophylactically against pneumonia.

During the following twenty-one months amphetamine was used as stimulant. An intravenous injection of 20–50 mg (according to the estimated depth of the narcosis) was given at once, followed by 50 mg per hour, generally intramuscularly. In a few very serious cases 100 mg per hour was given for short periods. As a prophylactic measure against pneumonia penicillin, in a few cases combined with sulphonamide, was used.

RESULTS

The material has been divided into slight and severe cases. Severe cases comprise patients who were comatose on, or at some time after, admission. The rest are grouped as slight. The division into these two groups has been based exclusively on the objective condition of the patients, regardless of the sort and amount of hypnotic ingested and the time which had elapsed from the moment it had been taken and the time of the patient's admission.

Nikethamide Series

For the first 61 patients (45 women and 16 men) nikethamide was used (table I). Of these 27 died, giving a mortality of 44%. In "severe cases" the mortality was 63%. All but 1 of the 27 died within forty-nine hours of admission, 4 of them within the first six hours. (Of these 4, 3 were moribund on admission.) The remaining patient died seventy-four hours after admission. No patient survived who was unconscious for more than nine hours after admission.

The course was highly variable. One patient was awake on admission, but, in spite of vigorous stimulation, increasing somnolence and finally coma developed, and death followed thirty-nine hours after admission. In 9 cases the patient woke up after stimulation for some time and remained at least partially conscious for as long as thirty-six hours, after which, despite continuous stimulation, became unconscious again and died. In 7 cases circulatory shock developed, manifested by a weak, rapid pulse, pallor, cyanosis, decreasing blood-pressure, and increasing haemoglobin percentage. In most cases it did not develop until the patients were deeply comatose and their clinical condition very critical, in a few, however, it developed so rapidly that the patients succumbed before any anti-shock treatment could be instituted. All the patients who had shock died, even where blood transfusion was undertaken.

Side effects of nikethamide were seen in 76% and were often very embarrassing (table II). Signs of irritation

TABLE I—DISTRIBUTION OF INTOXICATIONS ACCORDING TO POISONS INGESTED AND SEVERITY OF CASES (SEE TEXT ABOUT THE DIFFERENCE OF "SEVERE" CASES IN THE TWO SERIES)

Poison	Nikethamide			Amphetamine		
	No. of cases	Type of case		No. of cases	Type of Case	
		Slight	Severe		Slight	Severe
Allyl isopropyl barbiturate	24 (40%)	4	20 (83%)	38 (44%)	20	20 (50%)
Phenyl-ethyl barbiturate	6 (10%)	3	3 (50%)	26 (20%)	17	9 (33%)
Other barbiturates	19 (30%)	6	13 (68%)	33 (25%)	17	16 (48%)
Unknown hypnotics	12 (20%)	5	7 (58%)	15 (11%)	11	4 (27%)
Total	61	18	43 (70%)	132	74	58 (44%)

of motor nerve centres (tremor, quivering, muscular rigidity, and trismus), which occurred in 16 of the 43 severe cases, sometimes necessitated withdrawal or reduction of dosage, and this also proved necessary in 2 cases where convulsions developed. Vomiting, which was found in 18 (42%) of the 43 unconscious patients, sometimes persisted for a long time and must be regarded as a very serious side effect, mainly because the danger of aspiration into the lungs is considerably increased, but also because carbon may be lost from the stomach, electrolytes and fluid are certainly lost. Sneezing, which occurred in 24 of the severe cases, sometimes persisted incessantly for several days. Psychic excitation and motor unrest may be caused by the barbiturates alone and are not necessarily due to nikethamide.

These poor results, which we were inclined to attribute, at least partially, to nikethamide, made us replace this drug by amphetamine.

Amphetamine Series

For the subsequent 132 patients amphetamine was used instead of nikethamide (table I). Of these 12 died, giving a mortality of 9%. In "severe" cases the mortality was 21%. In 9 cases death took place within forty-nine hours of admission, of these patients, 2

TABLE II—SIDE EFFECTS

Side-effect	No. of cases	
	Nikethamide	Amphetamine
Sneezing	26 (45%)	0
Vomiting	21 (34%)	15 (11%)
Cough	12 (20%)	0
Tremor rigidity	16 (26%)	3 (2%)
Convulsions	2 (3%)	0
Unrest, excitation	8 (13%)	6 (5%)
Headache	7 (11%)	10 (7%)
Dizziness	2 (3%)	4 (3%)
Confusion euphoria	0	6 (5%)
Hallucinations	0	2 (2%)
Extrasystoles	0	1 (1%)
Diplopia	0	2 (2%)
Total	41 (67%)	37 (28%)

were moribund on admission and died within six hours. The remaining 3 deaths occurred sixty-five, seventy, and a hundred and ten hours after admission.

Of the surviving patients, 4 woke up after more than seventy-two hours' unconsciousness, 1 of them after eighty-four hours. 6 were unconscious for forty-eight to seventy-two hours, 5 for twenty-four to forty-eight hours, 15 for six to twenty-four hours, and the remaining 28 for less than six hours.

The course of the individual cases changed completely when we began to use amphetamine instead of nikethamide. In contrast to what was seen with the nikethamide treatment, none of the patients who were conscious on admission became worse and died, and when coma subsided we could be confident that the patient was recovering. Even the severe cases with protracted coma did not present so many threatening symptoms as did the cases in which nikethamide was used, and when serious complications, such as shock, supervened these could be successfully treated. Fewer and less dangerous side effects occurred, and in no case was it necessary to interrupt the treatment because of side effects.

Case 1—A woman aged 34, was admitted four hours after having taken allyl isopropyl barbituric acid 5 g and diethyl barbituric acid 5 g in solution. She was deeply comatose, cyanotic and without reaction to pain, tendon and corneal reflexes were absent. After eighty-four hours treatment with amphetamine (total dose 4850 mg) she woke up and had no discomfort attributable to the therapy. Her highest blood pressure during treatment was 165/115 mm Hg.

TABLE III—FIFTY-FOUR SEVERE CASES IN AMPHETAMINE SERIES DISTRIBUTED ACCORDING TO HIGHEST BLOOD-PRESSURE, COMPARED WITH AVERAGE DOSE OF AMPHETAMINE IN CORRESPONDING GROUPS FIGURES IN PARENTHESES SHOW SMALLEST AND LARGEST DOSES GIVEN IN RESPECTIVE GROUPS

Highest systolic blood pressure (mm Hg)	No of cases	Dose of amphetamine (mg) average min and max.
100-150	22	1026 (50-4000)
150-175	20	1908 (75-4850)
175-200	9	1843 (100-2826)
200-250	3	1762 (1340-2075)

Case 2—A woman, aged 35, was admitted after having taken an unknown amount of some soporific at an unknown time. She was deeply comatose and did not respond to pain. She was cold and sweating, with imperceptible pulse and unmeasurable blood pressure. After treatment with amphetamine for twenty hours (total dose 1075 mg) she woke up and had no discomfort attributable to the therapy.

As a curiosity it may be mentioned that a pregnant woman at full term, who was admitted with severe poisoning with allylisopropyl barbituric acid, was delivered of a completely normal child during the treatment. She did not wake up until four hours after the delivery. By that time she had been treated with amphetamine for thirty-two hours (total dose 1525 mg) and owing to circulatory shock she had received a blood transfusion.

Side-effects (table II) were seen in 28% of the patients treated with amphetamine, but in all cases they were slight and only transitory. Thus, vomiting occurred in only 7% of the severe cases as compared with 42% in the nikethamide series, and most of the patients vomited only once. As is indicated in table II, side effects were much less frequent than in the nikethamide series.

In 13 patients electrocardiography was done after the treatment—in 9 within the first twenty-four hours after treatment had been discontinued. The electrocardiograms in 11 cases, including that of a patient who had received 4850 mg of amphetamine, were normal. One patient had low T_1 and T_2 and inverted T_3 waves, though the electrocardiogram had been normal two years previously. This patient, aged 45, was a chronic addict to alcohol and had had delirium tremens twice during the past two years, and it is unlikely that the changes were due to the amphetamine. The remaining patient was known to have heart disease with bundle branch block, and the electrocardiogram was unchanged after the amphetamine treatment.

The effect of amphetamine on the blood pressure is difficult to assess, because the blood pressure is also affected by several other factors in the treatment. If, arbitrarily, it is assumed that rises of the systolic blood-pressure above 150 mm Hg are produced by amphetamine, more than half of the severe cases had a rise in the blood pressure of this kind (table III). Table III also shows that there is no definite relation between the dose of amphetamine and the greatest height of blood pressure reached.

The blood-pressure remained high for one or two hours and then fell spontaneously to more moderate levels. In no case was it thought necessary to withdraw amphetamine because of raised blood pressure. In 2 cases amphetamine 100 mg per hour was given for three and twelve hours without any change in blood pressure. In 1 of them extrasystoles and slight tremor were observed, but these symptoms subsided as soon as the dose was reduced to the usual 50 mg per hour, the other patient had no discomfort whatever from the treatment. The patient with bundle branch block had for several years had a blood pressure of about 220/150 mm Hg. He was aged 60, and in four hours he received 250 mg

of amphetamine. During the treatment the blood-pressure fell from 220/150 to 170/105.

The figures for slight cases of poisoning do not allow any definite conclusions about changes of blood pressure, but they point in the same direction as those mentioned above.

It thus seems that the effect of amphetamine on the blood pressure does not restrict its use in the treatment of acute barbiturate poisoning. Pre-existing hypertension is no contra-indication.

DISCUSSION

In the two series the age distribution is uniform and the information obtained about the type and amounts of the hypnotics and the time of their ingestion does not differ materially. In the amphetamine series only 44% of the intoxications were "severe" cases, compared with 70% in the nikethamide series, but, according to the definition, assessment of severity depends on the efficacy of the therapy, and it is highly probable that this difference between the two series is due to the pronounced "exciting" effect of amphetamine. In the nikethamide series several patients who were awake became unconscious during the treatment, and according to the definition they were then placed under the heading "severe cases," whereas this happened in only 1 case among those treated with amphetamine.

As previously stated, apart from the stimulant used the treatment was essentially the same in the two series. The change from sulphonamides to penicillin cannot have altered the mortality, since none of the patients had massive or extensive pneumonia, and in only 1 case can bronchopneumonia (found at necropsy) be interpreted as the cause of death.

Blood transfusion was given in 33% of the severe cases in the amphetamine series, compared with 16% in the nikethamide series. The indications for transfusion were the same throughout the entire period. The difference must therefore be taken as an expression of the greater efficacy of amphetamine therapy, because the frequency of the presence of these indications will increase with the time of survival of severely poisoned patients. It has already been mentioned that the patients treated with nikethamide were more often in a more critical condition than those treated with amphetamine when the shock appeared. In the nikethamide series all 7 patients who were given blood-transfusions died, whereas in the amphetamine series 12 survived out of the 19 thus treated.

In both series moderate deviations from normal of the serum chloride, serum bicarbonate, and blood urea levels were seen in patients who were unconscious for long periods, but these deviations could be compensated by the daily administration of fluid without special measures being taken.

The temperature was alike in the two series. It was high in most severe cases and showed a tendency to increase with the duration of the coma. Antipyretics were of no avail, whereas direct cooling was often of use in reducing the temperature.

The neostigmine treatment cannot be said to have abolished the paralyzing effect of the barbiturates on the intestines, but in several cases, even in deeply comatose patients, a rapid action of neostigmine was seen, as shown by rectal evacuation of carbon about an hour after the first injection of the drug. The effect seems to have been best in the nikethamide series, presumably because amphetamine to some extent inhibits peristalsis.

There seems to be no reason for questioning the uniformity and comparability of the two series, and the unproved results obtained by the change from nikethamide to amphetamine—a decrease of the mortality figure from 44% to 9%—must therefore be considered significant.

certain bulk of Rh negative cells rather than with a certain volume of Rh negative blood this objective will be more easily attained by transfusing a concentrated suspension of erythrocytes rather than whole blood.

Mollison and Cutbush (1948) demonstrated that these considerations were of practical importance. They published details of one case in which they had measured the rate of red cell exchange using a differential agglutination method. After the exchange of some 240 ml of blood almost 90% of the red cells in the infant's circulation were Rh negative. They pointed out that according to some published formulae for exchange transfusion—e.g., of Wiener and Wexler (1946)—this degree of "exchange" should have been achieved only after replacing some 500 ml of blood. They also pointed out that the result was due to two separate factors: the initial anaemia of the infant and the high red-cell count of the donor blood. In another case they observed that, although at the end of an exchange transfusion some 90% of the cells were Rh negative the total red cell count was only about 3 000 000 per c mm. Thus although a satisfactory exchange of red cells had been made, the infant soon had to be given another transfusion. The last case illustrates well the shortcomings of describing the results of replacement transfusion in terms of "percentage exchange". It seems desirable to analyse more precisely the effects of replacement transfusion and to provide data from which the results in a given case can be predicted.

THEORETICAL CONSIDERATIONS

Wallerstein (1946) cited the results of calculations on the efficiency of exchange transfusions for two individual cases. Wiener and Wexler (1946) presented a more general formula, applicable in cases where the method of continuous transfusion and withdrawal was used. Subsequently Wallerstein and Brodie (1948) made a detailed theoretical study of various methods of making exchange transfusions in which they considered both the continuous and intermittent techniques and, in addition, some variations of these methods.

Experiments *in vitro* such as those reported by Wallerstein (1946) and Farquhar and Lewis (1949) are of little value, in that they only illustrate results already obtainable by mathematical calculations. Such calculations as those of Wallerstein and Brodie (1948) have proved useful in assessing the comparative value of different techniques but do not provide a very good basis for quantitative predictions, if the object of the exchange transfusion is to exchange red cells rather than blood.

The mathematical analyses and experiments *in vitro* of previous workers are only valid on the assumption that one homogeneous fluid is being replaced by a similar homogeneous fluid in a vessel of constant volume. Even in the apparently simple case where the haematocrit of the donor's blood is the same as that of the infant's blood it is impossible to apply these simple formulae to red-cell exchange without appreciable errors because the red cells are not uniformly distributed throughout the vascular system.

To derive an expression applicable to the exchange of red cells it is necessary to introduce a quantity k ,

which is the value of the ratio of the "whole body haematocrit" of the infant to the venous haematocrit. This constant has a value of about 0.87 and does not depend on the level of venous haematocrit (Mollison et al 1950).

Only the method of "intermittent substitution with equal volume replacement" is considered here—i.e. withdrawal of v ml of blood from the infant, followed by injection of v ml of blood into the infant &c. Now in such a case, if the blood volume of the infant (assumed to be constant during the exchange transfusion) is V ml, v ml is removed and replaced at each operation, H_o is the initial venous haematocrit of the infant's blood, D is the haematocrit of the donor's blood, and l is the constant referred to above, it can be shown that after n operations the fraction of the infant's original cells remaining is given by the formula

$$\frac{H}{H_o} = \left(1 - \frac{v}{kV}\right)^n \quad (1)$$

where H is the venous haematocrit of Rh positive cells after n operations.

The total venous haematocrit after n operations is given by

$$H_n = H_o \left(1 - \frac{v}{kV}\right)^n + D \left(1 - \left(1 - \frac{v}{kV}\right)^n\right) \quad (2)$$

The first term in equation 2 represents the residual Rh positive red cells and the second term the Rh-negative donor cells. Consequently the ratio of infant's original red cells to total red cells is given by

$$F = \frac{H_o \alpha^n}{H_o \alpha^n + D(1 - \alpha^n)} \quad \text{where } \alpha = \left(1 - \frac{v}{kV}\right) \quad (3)$$

It is a simple matter to modify equation 1 to make it applicable to various other techniques, but the case of "intermittent substitution with equal volume replacements" has been selected as being the most suitable for checking experimentally. Moreover, this technique is widely used.

METHODS

To test the assumptions made in deriving the above formula, studies were made of the efficiency of red cell exchange by studying the changes in concentration of red cells labelled with radioactive phosphorus (P^{32}). The donor blood used was freshly drawn and heparinised. In one case the haematocrit of the donor blood was raised artificially by centrifuging the blood and then removing some of the supernatant plasma. A small sample was taken from the donor bottle for the preparation of a radioactive cell suspension, and this was used for the determination of the infant's circulating red cell volume immediately before the beginning of the replacement transfusion. At the same time the plasma volume was determined by Evans blue (T-1824) dye method. A full description of these methods has been published elsewhere (Mollison et al 1950).

Throughout this paper, unless otherwise stated, "haematocrit" means the true proportion of red cells in unit volume of blood. Following Barnes et al (1948) we take the true venous red cell haematocrit to be the

The antagonism of amphetamine to the barbiturates has previously been described. Alles (1933) showed that amphetamine sulphate had a considerable stimulating effect on animals in barbiturate anaesthesia. Reifenstein and Davidoff (1938) showed that the depth and duration of 'Sodium amytal' narcosis in schizophrenics decreased considerably after the intravenous injection of amphetamine. While the patients were under the influence of amphetamine the blood pressure was raised, and the pulse rate either remained unchanged or decreased a little. On awakening, such patients might be somewhat euphoric or depressed and restless, might quiver a little, or complain of headache. All these side effects were, however, only of short duration. Myerson et al (1939) also used schizophrenics as experimental subjects. With sodium amytal a deep reactionless sleep was induced, from this they could be awakened with amphetamine in ten to twenty minutes. If amphetamine was given with the sodium amytal, or before it, the soporific action of the latter was abolished. The patients invariably showed a slower pulse rate and a raised blood pressure while they were under the influence of amphetamine, but no relation could be demonstrated between the rise of blood pressure and the stimulating effect. In experiments on animals Lumière and Meyer (1938) found that the stimulating effect of amphetamine was greater than that of strychnine, and Chakravarti (1939), who investigated the stimulating effect of amphetamine, leptazol, nikethamide, ephedrine, picrotoxin, and strychnine on animals, found that, in proportion to their toxicity, amphetamine had the most powerful effect, nikethamide the weakest, and leptazol one between these two extremes.

The pharmacology of amphetamine was described in some detail by Myerson (1940).

Sympathomimetic Effects

(1) It dilates the pupils, widens the palpebral apertures, increases the intra ocular tension, and diminishes the power of accommodation.

(2) It relaxes the non striated muscles of the gastro intestinal tract, weakens peristalsis, dilates the renal calyces and pelves and the bladder, and enlarges the kidneys.

(3) It causes a rise of the blood pressure for one or two hours and tends to slow the pulse rate, but no cardiac changes can be demonstrated.

(4) It reduces the secretion of saliva and sweat.

Stimulation of Central Nervous System

Subcutaneous or intravenous amphetamine 20-30 mg counteracts the hypnotic action of the barbiturates.

The only clinical study on amphetamine treatment of barbiturate poisoning was published by Freireich and Landsberg (1940). They treated 14 cases of moderate and severe barbiturate poisoning with amphetamine, and only 1 died.

In the few patients of our amphetamine series who died in spite of the treatment, necropsy did not reveal any damage to organs which could be attributed to amphetamine, and in a careful study of the literature I have been unable to find any description of such damage. On the other hand, numerous reports have been published of cerebral damage following the administration of nikethamide and leptazol, the actions of which are similar because they may cause convulsions. The cerebral changes are ganglion cell degeneration, small haemorrhages, and lymphocytic infiltrations. Such changes have been described in man by Hassin (1939), Roback and Miller (1940), and Weil and Liebert (1940). Similar changes have been demonstrated in animals which had been given large doses of leptazol (Cleckley et al 1940, Finley and Brenner 1941, Liebert and Weil 1939, Nyberg 1938, Strecker et al 1939), even if the convulsions were prevented by ether anaesthesia. In barbiturate poisoning in man Smith and Wanscher (1942) found the same cerebral changes both after treatment with leptazol and with nikethamide but the assessment of these

findings is made difficult by the fact that barbiturate alone may produce similar changes (Hassin 1939).

On the whole the clinical results of the present study agree well with those of previous experiments.

SUMMARY

61 patients with acute barbiturate poisoning were treated with nikethamide 2-5 g per hour, and 13 patients were treated with amphetamine, generally 50 mg per hour.

Apart from this, the two series were treated similarly—i.e., by aspiration of the stomach and instillation of medical carbon, stimulation of peristalsis with neostigmine, prophylactic treatment against pneumonia, the administration of parenteral fluid and anti shock treatment. The two last mentioned therapeutic measures were taken when judged necessary according to certain examinations mentioned which were carried out at brief intervals.

Of the 61 patients in the nikethamide series 27 (44%) died, the mortality for the 43 "severe" cases was 63%. Of the 132 patients in the amphetamine series 12 (9%) died, the mortality for the 58 "severe" cases was 21%. In the cases treated with amphetamine the course was less eventful, and the condition of the patients far better, than in those treated with nikethamide. Unfavourable effects were fewer and of little practical importance. This applies also to the rather common rise of blood pressure.

Hence it must be said that in the treatment of acute barbiturate poisoning amphetamine is far more effective than nikethamide.

THE RATE OF RED-CELL EXCHANGE IN REPLACEMENT TRANSFUSIONS

N VEALL

P L MOLLISON

B Sc Lond A Inst P

M.D Camb, M.R.C.P.

From the M.R.C. Radiotherapeutic Research Unit and Blood Transfusion Research Unit, Postgraduate Medical School of London

REPLACEMENT transfusion, as a form of treatment for haemolytic disease of the newborn, has been widely practised during the past two or three years. Broadly speaking, the object of this form of treatment is to remove as much as possible of the infant's blood and to replace it by Rh negative blood. However, if this objective is analysed, it will be found that it makes a great deal of difference whether it is whole blood or red cells only that are to be exchanged. If it is whole blood an equally large exchange transfusion will have to be carried out whether or not the infant is anaemic, but if the object is to remove as great a proportion as possible of the infant's red cells it is evident that the more anaemic the infant is the smaller will the exchange transfusion need to be. Similarly if another object of exchange transfusion is to supply the infant with a

the observed figures, and it seems that the most likely cause of the discrepancy is the change in blood volume during exchange transfusion. On the other hand, if the observed figures for total haematocrit and haematocrit of residual blood are corrected to allow for the observed increase in blood volume they exceed the expected values.

Although the observed increases in blood volume were similar in the three cases, these estimates are subject to considerable error. Each blood volume estimate entails the separate estimate of red cell volume and plasma volume, and the observed difference between two such estimates may carry an accumulated error. On theoretical grounds blood volume is expected to increase to a small extent as venous haematocrit increases (Mollison et al 1950). This change in blood volume may be regarded as "permanent". The present estimates suggest that there may be in addition a temporary increase in blood volume after replacement transfusion. Possibly, if the estimates of blood volume had been repeated at a longer interval after replacement transfusion, better agreement between the estimates would have been found. However, even if the observed increase in blood volume is both significant and permanent, the theoretical predictions, based on the assumption that the blood volume remains constant, still agree with experimental observations to within a small percentage and are certainly adequate for practical applications.

The fact that the blood flowing in the larger vessels contains a higher proportion of red cells than the average has an appreciable effect, as is shown by the difference between the solid and the interrupted lines in fig 1. This leads to a more rapid removal of the infant's red cells than would otherwise be the case, but, on the other hand, it also means that the removal of plasma is correspondingly less efficient. Thus by similar reasoning to that used for the formulae for red cells, the proportion of the infant's original plasma to total plasma (F_1) after n operations can be shown to be

$$F_1(\text{plasma}) = \frac{(1-H_0)\left(1-\frac{v}{xV}\right)^n}{(1-H_0)\left(1-\frac{v}{xV}\right)^n + (1-D)\left(1-\frac{v}{xV}\right)^n}$$

where the constant $x = \frac{1-W_0}{1-H_0}$, W_0 being the initial whole body haematocrit. This constant, unlike l , is greater than unity, hence the lower efficiency of plasma exchange compared with that of red cells.

PRACTICAL APPLICATIONS

Before we consider the practical application of the formulae given above, it is necessary to define the objective of the exchange transfusion in quantitative terms. After a consideration of the therapeutic requirements and the practical limitations, Wallerstein and Brodie (1948) concluded that it was desirable to proceed with an exchange transfusion until 90% of the infant's blood had been exchanged. However, they were considering the exchange only in terms of whole blood and, as we have shown, this is a different matter from considering the exchange of red cells alone. Now it is generally accepted that the object of the exchange is to reduce the haematocrit of Rh positive cells to a low level while providing sufficient Rh negative cells to prevent anaemia. Consequently it is suggested that for practical purposes the objectives of the exchange transfusion should be twofold:

- (1) the reduction of Rh positive cells to a level corresponding to a venous haematocrit of 5% ;
- (2) the addition of sufficient Rh negative cells to bring the total venous haematocrit up to not less than 50%.

Stating Wallerstein and Brodie's criterion in this form makes it possible to take into account two important variable factors which would otherwise be neglected: the haematocrit of the infant's original blood, and that of the donor blood.

Fig 2—Nomograms for replacement transfusions to reduce the haematocrit of the infant's own red cells to 5% and to leave the infant with a final haematocrit of 50%. Note that by using a concentrated red-cell suspension the injection of additional blood at the end of the exchange procedure is rendered unnecessary.

observed venous red cell haematocrit $\times 0.95$, on the assumption that 5% of the column consists of trapped plasma. The conditions of centrifugation are given in the paper referred to above.

The replacement transfusion was made in accordance with the technique described by Mollison and Cutbush (1948), a 20 ml syringe being used. Care was taken to prevent sedimentation in the bottle of donor blood and to measure as accurately as possible the volumes withdrawn and replaced. Samples of the discarded blood were taken at known intervals and measured for radioactivity. After an arbitrary number of operations the circulating red cell and plasma volumes were redetermined with further injections of radioactive red cells and Evans blue, the samples obtained being corrected for any residual radioactivity and dye left from the previous determinations.

In two cases the proportion of infant's red cells remaining in the circulation was also deduced from estimations made by the technique of differential agglutination, as follows.

The red cell count of the donor blood was estimated by counting about 2000 cells, mean corpuscular volume (M.C.V.) was determined in the conventional manner from red cell count and venous haematocrit. The infant's initial red cell count and M.C.V. were determined in the same way from a venous blood sample. The proportion of infant's red cells remaining in the blood after n operations was determined by subtracting estimates of donor red cell count from estimates of total red cell count, the number of donor cells being determined by the technique of differential agglutination. The proportion of infant's red cells in the blood after a given number of operations may be expressed either in terms of relative number of red cells or in terms of relative volume of red cells. Since the red cells of a newborn infant are much larger than those of an adult, it makes a considerable difference whether one speaks of number or of volume. To obtain figures which could be compared with the P^{32} measurements the counts of donor's red cells and of infant's red cells (obtained by subtracting the count of donor's red cells from the total red cell count) were multiplied by observed M.C.V. to obtain their approximate proportion by volume.

RESULTS

The results obtained in three cases studied are shown in table I. The blood volume V is obtained by taking the sum of the measured red cell and plasma volumes and adding 2% to allow for the white cells. The whole body haematocrit, $W\%$, is obtained by dividing the observed red cell volume by the blood volume V . The factor k is derived from the whole body haematocrit

TABLE II.—COMPARISON BETWEEN THE OBSERVED AND CALCULATED VALUES OF THE FRACTION OF INFANT'S RED CELLS REMAINING AFTER EXCHANGE TRANSFUSION. THE VALUES ARE EXPRESSED FIRSTLY AS A FRACTION OF THE INITIAL RED CELL VOLUME AND SECONDLY AS A FRACTION OF THE FINAL RED CELL VOLUME.

Fig 1.—Relationship of number of replacement operations, each of 20 ml to fraction of infant's own red cells remaining in three cases: solid lines show theoretical values calculated from equation 1 (see text); interrupted lines show theoretical values calculated from equation of Wallerstein and Brodie (1948) in which k is not taken into account and observed values based on radioactivity measurements are shown as plotting points.

and the initial venous haematocrit. The number of complete operations—i.e., 20 ml withdrawal followed by equal volume replacement—and the haematocrit of the donor blood are given in the table.

It is thus possible to substitute numerical values for all the constants in equation 2, and to calculate the venous haematocrit after a given number of operations. Calculated values are given in the table and can be compared with the observed values given. It will be seen that the observed values are all lower than expected. However, it will also be noted from the figures for the final blood volume and for the increase in blood volume that, although the theoretical expression was derived on the assumption that the total blood volume would remain constant, there was, in each case, an increase in blood volume, although no extra blood had been added.

By substituting numerical values in equation 1 it is possible to calculate the fraction of the infant's own red cells remaining at any stage. The solid line in fig 1 shows the theoretical values calculated from equation 1. The interrupted line is derived from the equivalent equation given by Wallerstein and Brodie (1948), which differs in that the constant k is not taken into account. The experimental points are based on the radioactivity measurements. Strictly speaking, the experimental points refer to the haematocrit of the infant's cells H_n after n operations, and any change in blood volume necessitates a corresponding correction in these values if they are to reflect accurately the changes in the volume of Rh positive cells remaining.

In table II some of the experimental readings shown in fig 1 have been used to calculate the haematocrit of Rh positive cells remaining after a given number of operations. From this figure and the observed haematocrit, one obtains the ratio of the infant's cells to total red cells. The corresponding calculated figure obtained by substituting numerical values in equation 3 is also shown. It will be noted that there is very good agreement between the observed and the theoretical figures. As an additional experimental check the values obtained by differential agglutination measurements (see above) are also given. These values are obtained by difference—i.e., total red cell volume minus total volume of donor cells—and are consequently subject to considerably greater error than the P^{32} measurements, which estimate the infant's red cell volume directly. Moreover, estimates of red cell count have had to be converted into estimates of red cell volume for comparison with P^{32} measurements.

DISCUSSION OF EXPERIMENTAL RESULTS

It has been shown that equation 3 predicts with a fair degree of accuracy the ratio of the infant's residual cells to total red cell volume at any stage of the exchange. This figure, being a ratio, is not directly affected by changes in the total blood volume. The calculated figures for the fraction of the infant's cells remaining and for the final haematocrit do not agree so well with

removal of plasma, it would be necessary to leave 460 ml. to carry out a sufficiently large exchange. It would still be necessary to inject extra blood at the end of the exchange transfusion, since the haematocrit of the donor blood would have been increased to only about 40%.

If it is necessary to use more than one bottle of stored blood, it will usually be found most convenient to proceed as follows: remove 200 ml or more of supernatant plasma from each of two bottles of stored blood, mix the remaining cell suspensions by pouring from one bottle to the other, and put about 500 ml of the mixture into one bottle and leave about 150 ml in the other. The cell suspension should have a haematocrit of about 55%.

For example, take the case of an infant weighing 9 lb (4.08 kg) with a haematocrit of 48%. The nomograms show that an exchange transfusion of 600 ml is required and that the use of donor blood with a haematocrit of 53% (64% in acid citrate dextrose) would make unnecessary any "topping up" at the end of the exchange transfusion.

RECOMMENDED PROCEDURE

In practice it usually is inconvenient to have to determine the haematocrit of the donor blood and of the infant before beginning the exchange transfusion. The following routine is therefore suggested.

It is assumed that the haemoglobin concentration of the cord blood sample will have been determined as a guide to treatment (Mollison and Cutbush 1949). Now, provided that the cord has been clamped as soon after birth as possible, it can be assumed that the haemoglobin concentration of venous blood will be only slightly greater in samples taken from the infant after birth. Thus if the infant's weight is known, a preliminary guess can be made of the size of exchange transfusion likely to be necessary. The decision is next made whether to prepare a concentrated suspension of erythrocytes from one bottle of stored blood or from two. In either case a mixed sample of the donor cell suspension is obtained: a sample of blood is taken from the infant at the beginning of exchange transfusion and while the transfusion is being given haematocrits of the donor's and infant's blood samples are determined. Then after 30 minutes, and before the transfusion is completed the necessary information will be available and it will be possible by reference to the nomograms to decide how large the exchange transfusion must be and whether any "topping up" will be necessary at the end.

If there are no facilities for determining the haematocrit, the scales provided in fig 3 can be used for the conversion of haemoglobin values into their equivalent haematocrit values.

It will be observed that, for a given haemoglobin concentration, infants have slightly higher haematocrit values than have adults—i.e., the mean corpuscular haemoglobin concentration (MCHC) of infants is lower. Although little emphasis has been laid on this difference in published reports, our own results, in normal and diseased newborn infants, show that the MCHC of newborn infants is about 32% compared with about 34% in adults. This difference is taken into account in fig 3. On both haematocrit scales the values refer to observed red cell haematocrit. The haemoglobin scale is marked in g per 100 ml, but is also marked in percentages for the convenience of those who use the "M R C Photometer," an instrument on which 100% is equivalent to 14.8 g per 100 ml.

SUMMARY

Previously published formulae for the efficiency of replacement transfusion have considered the exchange of whole blood. The present paper is by contrast concerned with the exchange of red cells. It is shown that, to derive a reliable formula for this purpose it is necessary

Fig 3—Conversion of haemoglobin values into haematocrit values.

to take into account (1) the infant's initial haematocrit, (2) the haematocrit of the donor blood and (3) the unequal distribution of red cells and plasma in the vascular system.

Relevant formulae are presented whose validity has been established experimentally by the use of red cells labelled with P³².

The objectives of exchange transfusion in haemolytic disease of the newborn have been redefined in the following terms: (1) to reduce the haematocrit of Rh positive cells to 5%, and (2) to add sufficient Rh negative cells to bring the total venous haematocrit to 50%.

Nomograms have been prepared from which the size of replacement transfusion required to achieve the above objectives in any given case can be rapidly deduced.

We are grateful to Prof James Young for facilities for carrying out this work in the department of Obstetrics, Hammersmith Hospital and Prof A A Moncrieff (department of Child Health) for permission to treat and to make observations on infants under his care.

DURING the period in which these 175 cases of simple papilloma were under observation, 85 cases of carcinoma of the bladder were recognised *de novo*, and 31 of the 175 thought to be simple ultimately proved to be malignant. Thus we see in what a high proportion bladder growths are or become malignant—about 45% in this series. Of the total of 260 cases only 55% continued to be simple. The danger that a growth may become malignant should always occupy the surgeon's mind and impress him with the need for regular cystoscopy, particularly where the growth is solitary (tables I and II).

AGE, SEX, AND SITUATION

For practical purposes papilloma of the bladder does not occur at all before the age of about 30, the incidence increases as the years advance, to reach a maximum in the 6th and 7th decades (table III). This higher incidence among the elderly is not due to a continuation of the

With the aid of the formulae given in equations 1 and 2 it is possible to decide in advance the steps required to achieve a satisfactory exchange of red cells as defined above, provided that the necessary numerical values can be substituted in the formulae.

It is certainly impracticable to determine the blood volume (V) for each case before starting the transfusion. However, provided that the infant is not in cardiac failure, it seems to be sufficiently accurate for this purpose to assume a blood volume equivalent to 80 ml per kg of body weight (see Mollison et al 1950).

The volume of blood (v) replaced at each operation is assumed to be 20 ml in all cases.

The value of k is taken as 0.87 for all cases, again on the basis of observations on normal and diseased infants made by Mollison et al (1950).

Thus for each individual case it is necessary to measure only the infant's haematocrit and body weight and the haematocrit of the donor blood. In practice it would be inconvenient to have to make the necessary calculations arithmetically before starting the exchange, and to avoid this inconvenience nomograms (fig 2) have been prepared.

Before describing the use of the nomograms, some of the principles which emerge from their use may be outlined. When the infant is anæmic and small, the exchange of a relatively small amount of blood will reduce the haematocrit of Rh positive cells to 5%. However, if only a small exchange transfusion is given, the concentration of Rh-negative cells in the infant's circulation will not have increased sufficiently by the end of transfusion, unless a very concentrated suspension of Rh negative cells has been used. In such a case the concentration of Rh negative cells can be further increased by two methods—either by continuing the exchange transfusion, or by injecting Rh negative blood into the infant without further withdrawal, an operation conveniently described as "topping up".

USE OF NOMOGRAMS

The use of the nomograms is best illustrated by a concrete example.

The infant's weight, in the present case 6 lb (2.72 kg), is marked on scale 1 in fig 2, and its haematocrit, in the present case 39%, on scale 3A. For convenience the scales are marked for observed red cell haematocrit—i.e., they are not corrected by the factor 0.95. The two marks are joined by a straight line (a in fig 2) whose point of intersection with scale 2 gives the number of exchange operations and volume of donor blood required to reduce the haematocrit of Rh positive cells to 5%. Thus in the present case, 18 operations, involving the use of 360 ml of donor blood, are required.

The uncorrected value of the infant's original haematocrit is next marked on scale 3B, and the uncorrected donor haematocrit on scale 4. Two scales for the haematocrit of the donor blood are marked on scale 4—scale A to be used when freshly drawn heparinised blood is used, and scale B to be used when the donor blood has been drawn into an acid citrate dextrose preservative solution. Under the latter conditions the cells undergo immediate swelling but revert to their original size within 24 hours of transfusion. The extent of this swelling varies considerably in different solutions and even between different blood samples taken into the same preservative solution. The solution which is in general use in Britain at present has the following composition:

2% disodium citrate (monohydrate)	100 ml
15% dextrose	20 ml
to be mixed with 420 ml of blood	

For convenience, we refer to this solution as "acid citrate dextrose". We have found that, when blood is taken into this particular solution, the cells swell by 15% to

25%. It has been considered sufficient for the present purpose to assume an average value of 20%. This swelling is maximal within an hour of mixing the blood with the preservative solution and does not change appreciably during normal periods of storage. To avoid the need for calculating the true haematocrit value of donor blood taken into acid citrate dextrose, the observed value is marked on scale 4B. In the present example it is assumed that the donor's blood has been freshly drawn into a small amount of heparin saline, and the observed haematocrit, 45%, is therefore marked on scale 4B. A straight line (b in fig 2) joining these two points is continued till it intersects the reference line (5). The point of intersection is next joined to the point on scale 7 corresponding to the infant's weight by a line (c in fig 2) which cuts the slanting scale 6 to give the volume of additional blood (about 40 ml in the present case) to be given at the end of the replacement transfusion to bring the haematocrit of Rh negative cells to 45%.

If line b cuts the reference line 5 below the point of no extra blood will have to be injected into the infant at the end of the replacement transfusion. Evidently, if donor blood with a haematocrit of, say, 60%—i.e., 72% in acid citrate dextrose—were used as a routine it would very rarely be necessary to inject any additional blood. On the other hand, if ordinary citrated blood, as supplied by blood supply depots, is used, it will always be necessary to inject additional blood at the end of the transfusion if the infant's haematocrit is to be raised to 50%, since citrated blood usually has a haematocrit of 32–36% (true) or 38–43% (observed).

From one point of view there is much to be said for using, as a routine, blood whose haematocrit has been raised to 60% (72% in acid citrate dextrose) by the removal of supernatant plasma. This makes it unnecessary to inject additional blood at the end of the transfusion. However, the preparation of a suspension of packed cells with a haematocrit of 60% is not always possible, for instance, the bottle of stored blood may not have settled adequately. Moreover, even if it is possible to prepare a bottle with such a high haematocrit, it will reduce the volume of cell suspension available from a single bottle of blood to, say, 320 ml. The exchange of such a small volume will often be insufficient to reduce the haematocrit of the infant's own cells to 5%. In such cases it becomes of interest to know whether the use of, say, 400 ml of a cell suspension with a haematocrit of 45% could achieve the defined objects of replacement transfusion—such a suspension could often be prepared from a single bottle of stored blood.

In the present example it was shown that for an infant weighing 6 lb (2.72 kg) with an initial venous haematocrit of 39% the exchange of 360 ml of blood would suffice for the attainment of the first objective—i.e., the reduction of the haematocrit of Rh positive cells to 5%. The present example also shows that if the heparinised donor blood had a haematocrit of 45%, about 40 ml would have to be injected at the end of the exchange transfusion without withdrawing any further blood from the infant, if the infant's haematocrit was to be raised to 50%. In this example, therefore, the intelligent use of a single bottle of stored blood would suffice to achieve the objects of exchange transfusion.

When the infant is of average size (7 lb, 3.18 kg) and has a haematocrit of about 47%, the use of a single bottle of stored blood will not achieve these two objectives. The nomograms show that an exchange of 460 ml would be required to reduce the haematocrit of Rh positive cells to 5%. Now, if the bottle of stored blood were used without being "concentrated," its haematocrit would be about 35%, and the nomograms show that an extra 120 ml of blood would have to be injected after the completion of the exchange transfusion. Alternatively, if the bottle of stored blood were concentrated by

removal of plasma, it would be necessary to leave 460 ml. to carry out a sufficiently free exchange. It would still be necessary to inject extra blood at the end of the exchange transfusion since the haematocrit of the donor blood would have been increased to only about 40%.

If it is necessary to use more than one bottle of stored blood, it will usually be found most convenient to proceed as follows: remove 30 ml. or more of supernatant plasma from each of two bottles of stored blood, mix the remaining cell suspensions by pouring from one bottle to the other; and put about 500 ml. of the mixture into one bottle and leave about 150 ml. in the other. The cell suspension should have a haematocrit of about 55%.

For example, take the case of an infant weighing 1 lb (408 g.) with a haematocrit of 48%. The nomograms show that an exchange transfusion of 600 ml. is required and that the use of donor blood with a haematocrit of 53% (64% in acid citrate-dextrose) would make unnecessary any "topping up" at the end of the exchange transfusion.

RECOMMENDED PROCEDURE

In practice it usually is inconvenient to have to determine the haematocrit of the donor blood and of the infant before beginning the exchange transfusion. The following routine is therefore suggested.

It is assumed that the haemoglobin concentration of the cord blood sample will have been determined as a guide to treatment (Mollison and Cutbush 1949). Now, provided that the cord has been clamped as soon after birth as possible, it can be assumed that the haemoglobin concentration of venous blood will be only slightly greater in samples taken from the infant after birth. Thus, if the infant's weight is known, a preliminary guess can be made of the size of exchange transfusion likely to be necessary. The decision is next made whether to prepare a concentrated suspension of erythrocytes from one bottle of stored blood or from two. In either case a mixed sample of the donor cell suspension is obtained: a sample of blood is taken from the infant at the beginning of exchange transfusion and while the transfusion is being given; haematocrits of the donor's and infant's blood samples are determined. Then after 30 minutes and before the transfusion is completed, the necessary information will be available and it will be possible by reference to the nomograms to decide how large the exchange transfusion must be and whether any "topping up" will be necessary at the end.

If there are no facilities for determining the haematocrit, the scales provided in fig. 3 can be used for the conversion of haemoglobin values into their equivalent haematocrit values.

It will be observed that, for a given haemoglobin concentration, infants have slightly higher haematocrit values than have adults—i.e., the mean corpuscular haemoglobin concentration (M.C.H.C.) of infants is lower. Although little emphasis has been laid on this difference in published reports, our own results, in normal and diseased newborn infants, show that the M.C.H.C. of newborn infants is about 32% compared with about 34% in adults. This difference is taken into account in fig. 3. On both haematocrit scales the values refer to observed red cell haematocrit. The haemoglobin scale is marked in g. per 100 ml., but is also marked in per centages for the convenience of those who use the "M.R.C. Photometer," an instrument on which 100% is equivalent to 14.5 g. per 100 ml.

SUMMARY

Previously published formula for the efficiency of replacement transfusion have considered the exchange of whole blood. The present paper is by contrast concerned with the exchange of red cells. It is shown that to derive a reliable formula for this purpose it is necessary

Fig. 3—Conversion of haemoglobin values into haematocrit values.

to take into account (1) the infant's initial haematocrit, (2) the haematocrit of the donor blood and (3) the unequal distribution of red cells and plasma in the vascular system.

Relevant formulae are presented, whose validity has been established experimentally by the use of red cells labelled with P^{32} .

The objectives of exchange transfusion in haemolytic disease of the newborn have been redefined in the following terms: (1) to reduce the haematocrit of Rh positive cells to 5%, and (2) to add sufficient Rh negative cells to bring the total venous haematocrit to 50%.

Nomograms have been prepared from which the size of replacement transfusion required to achieve the above objectives in any given case can be rapidly deduced.

AGE, SEX, AND SITUATION

For practical purposes papilloma of the bladder does not occur at all before the age of about 30, the incidence increases as the years advance, to reach a maximum in the 6th and 7th decades (table III). This higher incidence among the elderly is not due to a continuation of the

With the aid of the formulae given in equations 1 and 2 it is possible to decide in advance the steps required to achieve a satisfactory exchange of red cells as defined above, provided that the necessary numerical values can be substituted in the formulae.

It is certainly impracticable to determine the blood volume (V) for each case before starting the transfusion. However, provided that the infant is not in cardiac failure, it seems to be sufficiently accurate for this purpose to assume a blood volume equivalent to 80 ml per kg of body weight (see Mollison et al 1950).

The volume of blood (v) replaced at each operation is assumed to be 20 ml in all cases.

The value of k is taken as 0.87 for all cases, again on the basis of observations on normal and diseased infants made by Mollison et al (1950).

Thus for each individual case it is necessary to measure only the infant's haematocrit and body weight and the haematocrit of the donor blood. In practice it would be inconvenient to have to make the necessary calculations arithmetically before starting the exchange, and to avoid this inconvenience nomograms (fig 2) have been prepared.

Before describing the use of the nomograms, some of the principles which emerge from their use may be outlined. When the infant is anæmic and small, the exchange of a relatively small amount of blood will reduce the haematocrit of Rh positive cells to 5%. However, if only a small exchange transfusion is given, the concentration of Rh negative cells in the infant's circulation will not have increased sufficiently by the end of transfusion, unless a very concentrated suspension of Rh negative cells has been used. In such a case the concentration of Rh negative cells can be further increased by two methods—either by continuing the exchange transfusion, or by injecting Rh negative blood into the infant without further withdrawal, an operation conveniently described as "topping up".

USE OF NOMOGRAMS

The use of the nomograms is best illustrated by a concrete example.

The infant's weight, in the present case 6 lb (2.72 kg), is marked on scale 1 in fig 2, and its haematocrit, in the present case 39%, on scale 3A. For convenience the scales are marked for observed red cell haematocrit—i.e., they are not corrected by the factor 0.95. The two marks are joined by a straight line (a in fig 2) whose point of intersection with scale 2 gives the number of exchange operations and volume of donor blood required to reduce the haematocrit of Rh positive cells to 5%. Thus, in the present case, 18 operations, involving the use of 360 ml of donor blood, are required.

The uncorrected value of the infant's original haematocrit is next marked on scale 3B, and the uncorrected donor haematocrit on scale 4. Two scales for the haematocrit of the donor blood are marked on scale 4: scale A to be used when freshly drawn heparinised blood is used, and scale B to be used when the donor blood has been drawn into an acid citrate dextrose preservative solution. Under the latter conditions the cells undergo immediate swelling but revert to their original size within 24 hours of transfusion. The extent of this swelling varies considerably in different solutions and even between different blood samples taken into the same preservative solution. The solution which is in general use in Britain at present has the following composition:

2% disodium citrate (monohydrate)	100 ml
15% dextrose	20 ml
to be mixed with 420 ml of blood	

For convenience, we refer to this solution as "acid citrate dextrose". We have found that, when blood is taken into this particular solution, the cells swell by 15% to

25%. It has been considered sufficient for the present purpose to assume an average value of 20%. This swelling is maximal within an hour of mixing the blood with the preservative solution and does not change appreciably during normal periods of storage. To avoid the need for calculating the true haematocrit value of donor blood taken into acid citrate dextrose, the observed value can be marked on scale 4B. In the present example it is assumed that the donor's blood has been freshly drawn into a small amount of heparin saline, and the observed haematocrit, 45%, is therefore marked on scale 4A. A straight line (b in fig 2) joining these two points is continued till it intersects the reference line (5). The point of intersection is next joined to the point on scale 7 corresponding to the infant's weight by a line (c in fig 2) which cuts the slanting scale 6 to give the volume of additional blood (about 40 ml in the present case) to be given at the end of the replacement transfusion to bring the haematocrit of Rh negative cells to 45%.

If line b cuts the reference line 5 below the point e , no extra blood will have to be injected into the infant at the end of the replacement transfusion. Evidently, if donor blood with a haematocrit of, say, 60%—i.e., 72% in acid citrate dextrose—were used as a routine it would very rarely be necessary to inject any additional blood. On the other hand, if ordinary citrated blood, as supplied by blood supply depots, is used, it will always be necessary to inject additional blood at the end of the transfusion if the infant's haematocrit is to be raised to 50%, since citrated blood usually has a haematocrit of 32–36% (true) or 38–43% (observed).

From one point of view there is much to be said for using, as a routine, blood whose haematocrit has been raised to 60% (72% in acid citrate dextrose) by the removal of supernatant plasma. This makes it unnecessary to inject additional blood at the end of the transfusion. However, the preparation of 60% is not always possible, for instance, the bottle of stored blood may not have settled adequately. Moreover, even if it is possible to prepare a bottle with such a high haematocrit, it will reduce the volume of cell suspension available from a single bottle of blood to, say, 320 ml. The exchange of such a small volume will often be insufficient to reduce the haematocrit of the infant's own cells to 5%. In such cases it becomes of interest to know whether the use of, say, 400 ml of a cell suspension with a haematocrit of 45% could achieve the defined objects of replacement transfusion, such a suspension could often be prepared from a single bottle of stored blood.

In the present example it was shown that for an infant weighing 6 lb (2.72 kg) with an initial venous haematocrit of 39% the exchange of 360 ml of blood would suffice for the attainment of the first objective—i.e., the reduction of the haematocrit of Rh positive cells to 5%. The present example also shows that if the heparinised donor blood had a haematocrit of 45%, about 40 ml would have to be injected at the end of the exchange transfusion without withdrawing any further blood from the infant, if the infant's haematocrit was to be raised to 50%. In this example, therefore, the intelligent use of a single bottle of stored blood would suffice to achieve the objects of exchange transfusion.

When the infant is of average size (7 lb, 3.18 kg) and has a haematocrit of about 47%, the use of a single bottle of stored blood will not achieve these two objectives. The nomograms show that an exchange of 460 ml would be required to reduce the haematocrit of Rh positive cells to 5%. Now, if the bottle of stored blood were used without being "concentrated," its haematocrit would be about 35%, and the nomograms show that an extra 120 ml of blood would have to be injected after the completion of the exchange transfusion. Alternatively, if the bottle of stored blood were concentrated by

Cystoscopy done too soon after treatment can cause misgivings as to the real state of affairs. One should wait until all oedema resulting from the fulguration has fully settled. An interval of four weeks, or sometimes more, is ordinarily required.

TREATMENT

Fulguration through a cystoscope is the treatment of election for papillomata of the bladder. It is inapplicable

- 1 When malignancy can be recognised
- 2 When malignancy is still in doubt after preliminary fulguration.
- 3 When for one reason or another it is impracticable

For routine destruction of papilloma per urethram an irrigating cystoscope is needed, and the more efficient the irrigating system the more quickly can the fulguration be carried out. (One of us has his own instrument which has been specially constructed for the purpose.) For the smaller growths up to a diameter of about $\frac{3}{4}$ in, one treatment should suffice. Much bigger growths can be completely destroyed by one treatment, but when the bladder is inspected again, a month or so later, a remnant of growth is often found, requiring further treatment. Multiple moderate sized growths certainly require several applications. As already stated, at least a month should elapse before the patient is cystoscoped again, to allow oedema and separating slough to disappear, and, where there is no tendency to quick reappearance of growth, three months is a more satisfactory interval between treatments.

It can be very discouraging to find repeated crops of small sessile papilloma, but regular treatments seem in time often to reduce the rapidity of the appearance of further growths.

Technique of Fulguration per Urethram—It is far more satisfactory to perform fulguration in hospital as a rule the patient need not be detained for more than two days. A general anaesthetic is to be preferred, where the number of subsequent treatments is uncertain, spinal anaesthetics are not advisable.

Using the coagulating current on the Genito Urinary Company's diathermy machine, 3 units is about the right strength, if one has it too strong the insulating material on the electrode will be damaged. About every three minutes the electrode is changed and the instrument nurse cleans the metal tip with the edge of a discarded scalpel. A treatment should go on until the whole surface of the growth has been whitened by coagulation. Occasionally poor vision from bleeding will terminate the proceedings.

Postoperative Supervision—Every now and again, one observes a patient with pericystitis following cystoscopic fulguration. This means that the bladder wall has been involved in the burning more than was anticipated. Such a patient must be kept in bed under observation until all symptoms have subsided. On the other hand tenderness may increase, redness or oedema may appear, and there may be constitutional signs of toxæmia. This means that extravasation of urine has occurred, and a suprapubic incision is called for to drain the extravasated tissues. Although it is not essential, it is generally wise to drain the bladder as well, by a small tube suprapubically. An indwelling urethral catheter is not a good alternative, for the drainage may have to continue for a long time.

Clot retention from continual bleeding has been known to occur after fulguration, necessitating evacuation of the clot either per urethram or—if the means of urethral evacuation are not available—by suprapubic incision.

Open fulguration not only has a mortality not met with in fulguration per urethram, but obliges the patient to stay in hospital until the suprapubic wound heals.

Total cystectomy is justifiable where small sessile papillomata reappear so often after treatment that they get out of control.

Radium Implantation—Where cystoscopic appearances are those of malignant disease radium needles should be implanted through a suprapubic incision, or radon seeds used after which the bladder may be completely closed. Operation mortality is negligible, the immediate prognosis is good, and the long term results with both techniques are very much better than those of total cystectomy.

PROGNOSIS

One can never assure the patient with any certainty that vesical papillomata will not return. The frequency with which they reappear in another part of the bladder shows that there is some factor in the bladder wall itself which encourages their recurrence.

The growth with the best prognosis is the single villous tumour, which often does not reappear for years. On the other hand it may return after a long period. For example, one of us has seen a small villous papilloma in the bladder of a man aged 56 who had had a papilloma destroyed by cystoscopic diathermy by another surgeon twenty eight years before.

The growth most likely to recur is the non villous papilloma which is multiple and sessile.

THE FOLLOW UP

The above statements show how necessary it is to follow up all cases indefinitely, even though cystoscopy has shown them to be free of growth, particularly as we know that a quite large growth may be present in the bladder without causing symptoms. The course of events taken by 17 cases in this series, all of whom missed cystoscopy for four years or more, is striking evidence of the need for the regularity of this examination, for in 11 (64%) of them the growth had reappeared. In 10 of these there had been no symptoms at all.

An excellent rule is that, having found a bladder quite free of growth three months after treatment, one should perform cystoscopy again six months later, nine months after that, and then every twelve months.

As already mentioned, with repeated fulguration the tendency of papillomata to reappear may slow down in the course of years.

One of us has a patient who has been under treatment for about eighteen years, and only once has her bladder been seen free of growth. She refused—we think quite rightly—to have a total cystectomy. At her present age of 66, there are still papillomata but she enjoys good health and there is no sign of malignancy in the true sense although the laboratory report on a section of the growth removed at the first operation eighteen years ago pronounced it to be malignant.

A proliferative growth associated with ulceration, whether the latter be raised or excavated, means malignancy, and the patient is unlikely to live more than a year or two from the onset of the ulceration unless radium or radical treatment is carried out.

SUMMARY

This paper reviews 175 cases of simple papilloma of the bladder, 31 of which proved to be malignant, or became so. They form part of a series of 260 cases, in 45% of which malignancy was found.

Cystoscopic fulguration is recommended for all cases of papilloma of the bladder which appear to be simple, and at first, in all doubtful cases as a diagnostic measure. Implantation of radium or radon by the suprapubic route is successful in many malignant cases.

After successful treatment by fulguration, papilloma of the bladder may return even after many years. Regular cystoscopy is essential, so that reappearing growths may have prompt treatment.

TABLE I—TIME OF ONSET OF MALIGNANT CHANGE

Malignancy found	Solitary tumours	Multiple tumours	Total
At first examination	73	12	85
Within 1/2 year	3	4	7
After 1/2-1 year	2	3	5
" 1-2 years	1	3	4
" 2-3 "	2	2	4
" 3-4 "	1	1	2
After over 4 "	3	6	9
Total	85	31	116

These figures demonstrate that cases originally presenting as a frank carcinoma are commonly solitary

disease from early life, it commences with greater frequency as the years go by

Like stone in the urinary tract and renal neoplasms, papilloma is much commoner in the male than in the female, three to one according to table III

Although no part of the bladder is immune from the growth, it tends to appear at the base, in the early stages it is found an inch or so above the ureteric orifices on either the outer or the inner side. The next common situation is at any point of the circumference round the internal urinary meatus. And, as the advance of a long standing papilloma goes on, the intervening areas between these localities become the seat of further spread. Hence it is not unusual to see vegetations involving any part of the area comprising the lower parts of the posterior and lateral walls, the trigone, and the internal urinary meatus. The small multiple rapidly reappearing growths which are seen so soon after existing ones have been destroyed by diathermy are widespread in their distribution

CLINICOPATHOLOGICAL CLASSIFICATION

Because in most of these cases the growth is treated through a cystoscope, and it is almost impossible with this instrument to remove a mass of the growth which will include a portion of the adjacent bladder wall, biopsy specimens are unreliable and the cystoscopist must make his own diagnosis by inspection. The following are the features which should guide him

Villous Papilloma

Pedunculated and long fronds

Single or multiple

No quick further new growth after fulguration

Sessile Papilloma

Invariably multiple

Quick small further growths after fulguration

It has short fronds and sometimes occurs with a villous papilloma

Doubtfully Malignant

Sessile papilloma with area of necrosis

Undoubtedly Malignant

A sessile papilloma associated with a bald tumour or with bald nodules in the vicinity

Ulceration of a sessile papilloma

Sessile papilloma with a firm base (as indicated by probing with diathermy electrode)

Though the majority of bladder growths are not malignant, and do not become so, malignant disease is all too often found after treatment, and a careful watch by cystoscopy must therefore be kept. Of the 205 cases in

TABLE II—INCIDENCE OF MALIGNANCY RELATED TO MULTIPLICITY OF TUMOURS

Tumours	Total no of cases in group	No showing malignant change
Remaining solitary	129	72
Solitary becoming multiple	38	14
Apparently multiple from onset	83	30
Total	250	116

which no malignancy could be recognised at the first examination, 61 (21%) ultimately showed definite signs of a malignant change

SYMPTOMS

All papillomata tend to bleed as they get large, because necrosis takes place as a result of a diminishing blood supply. Haematuria is the almost constant sign with the outstanding feature that it is generally painless. Of the 260 cases under review, there were only 10 (3.8%) without haematuria, and 5 of these were malignant, moreover, the haematuria of vesical carcinoma is not usually painless.

When the urine is bloodstained and examined in two glasses, blood of vesical origin tends to be more concentrated in the second glass than the first. This is in contrast with blood of renal origin which is equal in both glasses. With blood of urethral or prostatic origin the first glass is darker than the second.

The higher concentration of blood in the second glass should not be confused with the terminal haematuria of cystitis, in which a few drops of blood are expressed at the end of micturition, and there is also increased frequency of micturition. But markedly terminal haematuria is sometimes seen with a papilloma when the growth is situated near the internal meatus. Persisting increased frequency of micturition usually means that malignancy has supervened, in which case dysuria is generally present as well.

TABLE III—AGE INCIDENCE

Age	Male	Female
29	1	
30-40	13	1
41-50	24	6
51-60	61	24
61-70	69	10
Over 70	27	
Total	195	45

The onset of haematuria has no fixed relation to the size of the growth. Some growths attain a considerable size before the first bleeding, others are still quite small. The determining factor is probably necrosis due to poor vascularity, and this may be expected sooner in a villous growth with long fronds than in a more compact vegetation. Bleeding because of malignancy puts the case into another category.

Some patients have increased frequency of micturition, and, as they often have residual urine too, there is the obvious suggestion that the papilloma is only part of the local pathology which has also led to bladder neck obstruction.

DIAGNOSIS

Cystoscopy makes diagnosis a simple matter. Difficulties arising from persistent bleeding can generally be overcome by irrigation throughout the examination. If at the first examination, because of bleeding, the view is too poor for a definite opinion to be formed, a short period of indwelling catheter drainage (24-48 hours), with bladder irrigation several times daily if necessary, will usually make it easier to see the growth. Where successful treatment per urethrum can be hoped for, one should avoid opening the bladder to make a diagnosis.

After a good view has been obtained, the question of malignancy may still be undecided. As a rule it can be answered, at a subsequent examination, carried out two weeks or more after vigorous treatment by fulguration.

It is a mistake to assume that a growth is malignant because it is very large. A papilloma may fill the whole bladder, and prevent a cystoscopic view, and on the suprapubic approach it may be so avascular that it can literally be raked out with the fingers without causing any troublesome bleeding.

by sending identical twins with whooping cough to the hospital. One of these children was used as a control and the other was given the 60 mg per kg dosage. Fig. 2 shows that the treated child's cough counts closely followed the curve of the children on 50 mg per kg until the last of the five days' observation, when it fell to 1-4 daily, though the cough was still hard and dry.

Chloramphenicol

Chloramphenicol was also given in two forms (1) an emulsion in lemon syrup containing 250 mg of chloramphenicol per drachm was used for infants up to 1 year of age, and (2) capsules, each containing 250 mg, were given to children over the age of 4 years. The treatment of children between the ages of 1 and 4 years is still a difficult problem, because of the extremely bitter taste of chloramphenicol and the objection of these children to swallowing capsules.

Whichever preparation was chosen, the dosage was 100 mg per kg of body-weight once daily, at bedtime, for five days. This routine was based on the observation that a single large dose of chloramphenicol almost completely sterilises the upper respiratory tract. Since *H. pertussis* is sensitive to chloramphenicol at relatively low concentrations, it seemed possible that such widely spaced doses would effectively control the disease, and the treatment would then be much simplified.

The results in the 21 treated cases are compared with the controls in fig. 3. It will be seen that the cough counts were greatly reduced by the chloramphenicol. By the twenty-third day of the disease the average count in the treated patients had reached the level that the controls attained on the forty-second day. In contrast with the children treated with aureomycin, those receiving chloramphenicol lost their whooping and vomiting and their cough became loose and productive.

Comments

Two unconnected points are worth noting. The first is the remarkable effect of aureomycin in the spersoid form on the children's appetite. Whooping cough is notorious for producing vomiting and a disinclination to eat. Yet by the fourth or fifth day of spersoid treatment, in spite of the persistence of vomiting after a paroxysm these children developed an almost pathological craving for food. So many mothers volunteered this information that notice had to be taken of it. None of the controls and none of the patients treated with

aureomycin capsules or with chloramphenicol gave a similar story.

The second point is the poor randomisation of cases which will be seen in the graphs. Despite the attempt to balance the numbers of cases of about similar severity in the treated and untreated groups, there was in fact a preponderance of the most severe cases in the treated groups. This maldistribution, which was not recognised until the data were analysed after completion of the tests, weighted the chances against the antibiotics and so added to the significance of any effects that they were shown to exert on the course of the disease.

DISCUSSION

It may be objected that this trial was wholly dependent on the mothers' estimates of progress, that they are unreliable witnesses, and that a satisfactory assessment of antibiotic treatment in whooping cough can only be made on cases treated in hospital.

Personal experience with information obtained from hospital sources has shown it to be of little value. The nurses, short handed and with a large number of ill children to look after, cannot be expected to produce accurate measurements of daily changes in so ephemeral a thing as a cough. In the end, the information is usually based on impressions gained from the physicians, house officers, and nurses, whose observations vary widely in reliability and regularity. In contrast, we have found the mothers conscientious and painfully accurate, because they have a vested interest in the children being treated and have but one patient to nurse.

It has been suggested that a better index would be the effect of the antibiotic on complications such as atelectasis, eclampsia, &c. Unfortunately, in whooping cough many of these tragedies are due to mechanical factors—plugging of bronchioles with mucus or of cerebral capillaries with lymphocytes—and an anti-bacterial substance cannot be expected to exert kinetic energy for the dislodgment of these blocks. However, an effective treatment, if given in time, must be able to prevent such complications. In the long run its efficacy in this respect can best be established by showing that it has produced a significant drop in the pertussis death rate in the Registrar General's returns. The method used in this trial seems to be the most satisfactory one for rapidly assessing the value of aureomycin and chloramphenicol in pertussis.

The results suggest that both aureomycin and chloramphenicol are effective in whooping cough. The findings with chloramphenicol confirm the apparent cures obtained at the same hospital in the pilot trial (Gray 1950) during last year's epidemic. In the U.S.A. Bell et al. (1949) treated 20 cases of pertussis with aureomycin and thought it shortened the disease, but striking results were only obtained when the drug was given in the early stages of the infection. Before the results with the two antibiotics are compared, it should be pointed out that the correct dosage of either has not yet been found. The impression gained from the present trial is that the amount of aureomycin given was too small, and that the clinical results might have been better with a dosage of 100 mg per kg daily in divided doses. The dosage of chloramphenicol used last year now seems unnecessarily high whereas this year's seems not quite high enough. A suitable intermediate dosage would be 100 mg per kg once a day (as in the trial) followed at eight hour intervals by two maintenance doses of 60 mg for infants of under a year, 125 mg for children of 1-3 years and 250 mg for those over 3 years.

The difficulty of administration to children of 1-3 years is said to have been overcome in the case of aureomycin by giving it in a palatable chocolate powder

Fig. 3.—Daily cough-counts in same controls as in fig. 1 compared with those of 21 patients treated with chloramphenicol 100 mg per kg of body weight for five days.

AUREOMYCIN AND CHLORAMPHENICOL
IN WHOOPING-COUGH

J D GRAY

M D McGill

PATHOLOGIST, BELGRAVE HOSPITAL FOR CHILDREN, AND ROYAL
EYE HOSPITAL, LONDON (KING'S COLLEGE HOSPITAL GROUP)

The preliminary survey of the effects of chloramphenicol in whooping cough described in a previous paper (Gray 1950), did not lead to any definite conclusions because the cases were too few and an untried method was used for assessing results. When this year's epidemic began the investigation was reopened and was extended to include a trial of 'Aureomycin'. The same method as before was adopted for gauging the progress of the "treated" and controlled children. The mother kept a written record of the number of paroxysms of all types that her child had in each 24 hours. The children were treated as hospital outpatients but were seen daily except at weekends.

No child was accepted for the trial unless three of the following four conditions were present: (1) an absolute lymphocytosis, (2) a normal erythrocyte sedimentation rate, (3) a paroxysm observed during a visit to the hospital, and (4) isolation of *Haemophilus pertussis* from a postnasal swab. For the bacteriological test a new selective medium (Lacey 1951) was tried. This returned 35% of the swabs as positive in the first month, 75% in the third month, and 84% in the final month, whereas parallel cultures on ordinary Bordet Gengou medium gave 50-55% positive plates. The poor early results with the new medium were due to inexperience.

On the day after the patients were first seen they were all started on four hourly doses of a chocolate milk sugar powder which was almost indistinguishable from one of the forms of aureomycin used. Between the third and fifth days, when the diagnosis was fully established, the cases chosen for antibiotic treatment were changed to either aureomycin or chloramphenicol which was continued for five days, after which they returned to the placebo powder and continued with this until then discharge. No child with a history of more than 20 days' illness was given antibiotic treatment. The average daily cough counts in the control and treated groups were plotted on graphs, which also showed the average day of disease on which the patients were first

seen and the average time elapsing between onset and the start of treatment.

RESULTS

Controls

The control curve in fig. 1 illustrates the normal course of the disease, without any specific treatment, in the 1950 epidemic. The average cough count on the day before the placebo was started was 26, with the institution of what the mothers looked upon as treatment it dropped to 18-22 per twenty-four hours, it stayed at this level for eleven days and then steadily declined to reach 5 coughs daily by the fortieth day of the disease. In general the trend followed that of the 1949 epidemic.

The graph suggests that giving the placebo powder had a slight psychological effect on the mothers, but this in no way invalidates the use of their cough-count as a yardstick for measuring the results of treatment.

Fig. 2—Daily cough-counts in identical twins aged 3 years and weighing 16 kg. each. One twin was given aureomycin 60 mg. per kg. of body weight daily for five days while the other was an untreated control.

Aureomycin

Two preparations of aureomycin were given: (1) 'Spersoid,' in which the aureomycin was dispersed evenly in a chocolate sugar powder, so that 3 g. (1 level teaspoonful) of the powder contained 50 mg. of active aureomycin, and (2) the usual capsules, each containing either 50 or 250 mg. Children up to 4 years were given spersoid. Over that age they received either 50 or 250 mg. capsules, depending on the child's ability to swallow. The daily dosage for the 38 cases was 50 mg. per kg. of body weight divided into four hourly doses. Treatment was continued for five days.

Fig. 1 shows the results with spersoid in 28 cases and with capsules in 10 cases. It seems clear that aureomycin in the spersoid form definitely reduced the cough count, thus by the twenty-second day of disease the average count of the patients treated in this way had reached the level attained by the untreated cases on the thirty-eighth day. On the qualitative side, however, the cough remained hard, and vomiting and whooping still continued. When the aureomycin was given in capsules the average cough counts were the same as in the controls until the final day of treatment when there was a fall suggesting that the treatment had some effect. As in the children given spersoid the cough in this group remained hard and the vomiting and whooping were not checked.

In a few cases the dosage of aureomycin in spersoid form was raised to 60 mg. per kg. daily for five days. There were not enough patients in this group to be comparable with the series given 50 mg. per kg. daily. However, fortune favoured this part of the inquiry.

Fig. 1—Daily cough-counts in 82 untreated control cases compared with those in cases treated with aureomycin 50 mg. per kg. of body-weight daily for five days: 28 receiving the drug in the form of spersoids and 10 in that of capsules.

by sending identical twins with whooping cough to the hospital. One of these children was used as a control and the other was given the 60 mg per kg dosage. Fig. 2 shows that the treated child's cough counts closely followed the curve of the children on 50 mg per kg until the last of the five days' observation, when it fell to 1-4 daily, though the cough was still hard and dry.

Chloramphenicol

Chloramphenicol was also given in two forms (1) an emulsion in lemon syrup containing 250 mg of chloramphenicol per drachm was used for infants up to 1 year of age, and (2) capsules, each containing 250 mg, were given to children over the age of 4 years. The treatment of children between the ages of 1 and 4 years is still a difficult problem, because of the extremely bitter taste of chloramphenicol and the objection of these children to swallowing capsules.

Whichever preparation was chosen, the dosage was 100 mg per kg of body weight once daily, at bedtime, for five days. This routine was based on the observation that a single large dose of chloramphenicol almost completely sterilises the upper respiratory tract. Since *H. pertussis* is sensitive to chloramphenicol at relatively low concentrations, it seemed possible that such widely spaced doses would effectively control the disease, and the treatment would then be much simplified.

The results in the 21 treated cases are compared with the controls in fig. 3. It will be seen that the cough counts were greatly reduced by the chloramphenicol. By the twenty-third day of the disease the average count in the treated patients had reached the level that the controls attained on the forty-second day. In contrast with the children treated with aureomycin, those receiving chloramphenicol lost their whooping and vomiting and their cough became loose and productive.

Comments

Two unconnected points are worth noting. The first is the remarkable effect of aureomycin in the spersoid form on the children's appetite. Whooping cough is notorious for producing vomiting and a disinclination to eat. Yet by the fourth or fifth day of spersoid treatment, in spite of the persistence of vomiting after a paroxysm, these children developed an almost pathological craving for food. So many mothers volunteered this information that notice had to be taken of it. None of the controls and none of the patients treated with

aureomycin capsules or with chloramphenicol gave a similar story.

The second point is the poor randomisation of cases, which will be seen in the graphs. Despite the attempt to balance the numbers of cases of about similar severity in the treated and untreated groups, there was in fact a preponderance of the most severe cases in the treated groups. This maldistribution, which was not recognised until the data were analysed after completion of the tests, weighted the chances against the antibiotics and so added to the significance of any effects that they were shown to exert on the course of the disease.

DISCUSSION

It may be objected that this trial was wholly dependent on the mothers' estimates of progress, that they are unreliable witnesses, and that a satisfactory assessment of antibiotic treatment in whooping cough can only be made on cases treated in hospital.

Personal experience with information obtained from hospital sources has shown it to be of little value. The nurses, short handed and with a large number of ill children to look after, cannot be expected to produce accurate measurements of daily changes in so ephemeral a thing as a cough. In the end, the information is usually based on impressions gained from the physicians, house officers, and nurses, whose observations vary widely in reliability and regularity. IN WHOOPING-COUGH

J D GRAY

M.D. McGill

PATHOLOGIST, BELGRAVE HOSPITAL FOR CHILDREN, AND ROYAL
EYE HOSPITAL, LONDON (KING'S COLLEGE HOSPITAL GROUP)

THE preliminary survey of the effects of chloramphenicol in whooping cough, described in a previous paper (Gray 1950), did not lead to any definite conclusions because the cases were too few and an untried method was used for assessing results. When this year's epidemic began, the investigation was reopened and was extended to include a trial of 'Aureomycin'. The same method is before was adopted for gauging the progress of the "treated" and controlled children. The mother kept a written record of the number of paroxysms of all types that her child had in each 24 hours. The children were treated as hospital outpatients but were seen daily except at weekends.

No child was accepted for the trial unless three of the following four conditions were present: (1) an absolute lymphocytosis, (2) a normal erythrocyte sedimentation rate, (3) a paroxysm observed during a visit to the hospital, and (4) isolation of *Hæmophilus pertussis* from a postnasal swab. For the bacteriological test a new selective medium (Lacey 1951) was tried. This returned 35% of the swabs as positive in the first month, 75% in the third month, and 84% in the final month, whereas parallel cultures on ordinary Bordet Gengou medium gave 50-55% positive plates. The poor early results with the new medium were due to inexperience.

On the day after the patients were first seen they were all started on four hourly doses of a chocolate milk sugar powder which was almost indistinguishable from one of the forms of aureomycin used. Between the third and fifth days, when the diagnosis was fully established, the cases chosen for antibiotic treatment were changed to either aureomycin or chloramphenicol which was continued for five days, after which they returned to the placebo powder and continued with this until their discharge. No child with a history of more than 20 days' illness was given antibiotic treatment. The average daily cough counts in the control and treated groups were plotted on graphs, which also showed the average day of disease on which the patients were first

seen and the average time elapsing between onset and the start of treatment.

RESULTS

Controls

The control curve in fig. 1 illustrates the normal course of the disease, without any specific treatment, in the 1950 epidemic. The average cough-count on the day before the placebo was started was 26, with the institution of what the mothers looked upon as treatment it dropped to 18-22 per twenty four hours, it stayed at this level for eleven days and then steadily declined to reach 5 coughs daily by the fortieth day of the disease. In general the trend followed that of the 1949 epidemic.

The graph suggests that giving the placebo powder had a slight psychological effect on the mothers, but this in no way invalidates the use of their cough-counts as a yardstick for measuring the results of treatment.

Fig. 2.—Daily cough counts in identical twins aged 3 years and weighing 16 kg. each. One twin was given aureomycin 60 mg per kg of body-weight daily for five days while the other was an untreated control.

Aureomycin

Two preparations of aureomycin were given: (1) 'Spersoid', in which the aureomycin was dispersed evenly in a chocolate sugar powder, so that 3 g (1 level teaspoonful) of the powder contained 50 mg of active aureomycin, and (2) the usual capsules, each containing either 50 or 250 mg. Children up to 4 years were given spersoid. Over that age they received either 50 or 250 mg capsules, depending on the child's ability to swallow. The daily dosage for the 38 cases was 50 mg per kg of body weight divided into four hourly doses. Treatment was continued for five days.

Fig. 1 shows the results with spersoid in 28 cases and with capsules in 10 cases. It seems clear that aureomycin in the spersoid form definitely reduced the cough count: thus by the twenty-second day of disease the average count of the patients treated in this way had reached the level attained by the untreated cases on the thirty-eighth day. On the qualitative side, however, the cough remained hard, and vomiting and whooping still continued. When the aureomycin was given in capsules the average cough counts were the same as in the controls until the final day of treatment when there was a fall, suggesting that the treatment had some effect. As in the children given spersoid, the cough in this group remained hard and the vomiting and whooping were not checked.

In a few cases the dosage of aureomycin in spersoid form was raised to 60 mg per kg daily for five days. There were not enough patients in this group to be comparable with the series given 50 mg per kg daily. However, fortune favoured this part of the inquiry.

Fig. 1.—Daily cough-counts in 82 untreated control cases compared with those in cases treated with aureomycin 50 mg per kg of body-weight daily for five days: 28 receiving the drug in the form of spersoids and 10 in that of capsules.

by sending identical twins with whooping cough to the hospital. One of these children was used as a control and the other was given the 60 mg per kg dosage. Fig. 2 shows that the treated child's cough counts closely followed the curve of the children on 50 mg per kg until the last of the five days' observation, when it fell to 1-4 daily, though the cough was still hard and dry.

Chloramphenicol

Chloramphenicol was also given in two forms: (1) an emulsion in lemon syrup containing 250 mg of chloramphenicol per drachm was used for infants up to 1 year of age, and (2) capsules, each containing 250 mg, were given to children over the age of 4 years. The treatment of children between the ages of 1 and 4 years is still a difficult problem because of the extremely bitter taste of chloramphenicol and the objection of these children to swallowing capsules.

Whichever preparation was chosen, the dosage was 100 mg per kg of body weight once daily, at bedtime, for five days. This routine was based on the observation that a single large dose of chloramphenicol almost completely sterilises the upper respiratory tract. Since *H. pertussis* is sensitive to chloramphenicol at relatively low concentrations, it seemed possible that such widely spaced doses would effectively control the disease, and the treatment would then be much simplified.

The results in the 21 treated cases are compared with the controls in fig. 3. It will be seen that the cough counts were greatly reduced by the chloramphenicol. By the twenty-third day of the disease the average count in the treated patients had reached the level that the controls attained on the forty-second day. In contrast with the children treated with aureomycin, those receiving chloramphenicol lost their whooping and vomiting and their cough became loose and productive.

Comments

Two unconnected points are worth noting. The first is the remarkable effect of aureomycin in the spersoid form on the children's appetite. Whooping cough is notorious for producing vomiting and a disinclination to eat. Yet by the fourth or fifth day of spersoid treatment, in spite of the persistence of vomiting after a paroxysm the children developed an almost pathological craving for food. So many mothers volunteered this information that notice had to be taken of it. None of the controls and none of the patients treated with

aureomycin capsules or with chloramphenicol gave a similar story.

The second point is the poor randomisation of cases which will be seen in the graphs. Despite the attempt to balance the numbers of cases of about similar severity in the treated and untreated groups, there was in fact a preponderance of the most severe cases in the treated groups. This maldistribution, which was not recognised until the data were analysed after completion of the tests, weighted the chances against the antibiotics and so added to the significance of any effects that they were shown to exert on the course of the disease.

DISCUSSION

It may be objected that this trial was wholly dependent on the mothers' estimates of progress, that they are unreliable witnesses, and that a satisfactory assessment of antibiotic treatment in whooping cough can only be made on cases treated in hospital.

Personal experience with information obtained from hospital sources has shown it to be of little value. The nurses, short-handed and with a large number of ill children to look after, cannot be expected to produce accurate measurements of daily changes in so ephemeral a thing as a cough. In the end, the information is usually based on impressions gained from the physicians, house officers and nurses, whose observations vary widely in reliability and regularity. In contrast, we have found the mothers conscientious and painfully accurate, because they have a vested interest in the children being treated and have but one patient to nurse.

It has been suggested that a better index would be the effect of the antibiotic on complications such as atelectasis, eclampsia, &c. Unfortunately, in whooping cough many of these tragedies are due to mechanical factors—plugging of bronchioles with mucus or of cerebral capillaries with lymphocytes—and an antibacterial substance cannot be expected to exert kinetic energy for the dislodgment of these blocks. However, an effective treatment, if given in time, must be able to prevent such complications. In the long run its efficacy in this respect can best be established by showing that it has produced a significant drop in the pertussis death rate in the Registrar General's returns. The method used in this trial seems to be the most satisfactory one for rapidly assessing the value of aureomycin and chloramphenicol in pertussis.

The results suggest that both aureomycin and chloramphenicol are effective in whooping cough. The findings with chloramphenicol confirm the apparent cures obtained at the same hospital in the pilot trial (Gray 1950) during last year's epidemic. In the U.S.A. Bell et al. (1949) treated 20 cases of pertussis with aureomycin and thought it shortened the disease but striking results were only obtained when the drug was given in the early stages of the infection. Before the results with the two antibiotics are compared, it should be pointed out that the correct dosage of either has not yet been found. The impression gained from the present trial is that the amount of aureomycin given was too small and that the clinical results might have been better with a dosage of 100 mg per kg daily in divided doses. The dosage of chloramphenicol used last year now seems unnecessarily high whereas this year's seems not quite high enough. A suitable intermediate dosage would be 100 mg per kg once a day (as in the trial) followed at eight-hour intervals by two maintenance doses of 60 mg for infants of under a year, 125 mg for children of 1-3 years, and 250 mg for those over 3 years.

The difficulty of administration to children of 1-3 years is said to have been overcome in the case of aureomycin by giving it in a palatable chocolate powder.

Fig. 3.—Daily cough-counts in same controls as in fig. 1 compared with those of 21 patients treated with chloramphenicol 100 mg per kg of body weight for five days.

vehicle But in my view this powder's content of aureomycin—50 mg in each teaspoonful—is too small Thus, a child weighing 15 kg, who is ordered a daily dosage of 50 mg of aureomycin per kg of body weight, will have to take fifteen teaspoonfuls of the chocolate powder every day—enough to lead most children to rebel after three or four days If the present aureomycin content was doubled, or better still trebled, the powder should be satisfactory The taste of chloramphenicol is harder to disguise, and so far no vehicle has been discovered which will wholly cover it up But the experienced nurse or mother can usually get the doses taken without much trouble

The association of a voracious appetite with aureomycin dosage is only seen when the antibiotic is given in a dispersed form, it was not reported in any case receiving aureomycin in gelatin capsules, which may be digested in the duodenum Aureomycin in spersoid, however, comes in close contact with the gastric mucosa, and the effect on appetite may depend on this fact The observation recalls the so called growth factor described as intimately related to aureomycin Is it possible that the increased growth noted in animals when this factor is added to their feeds is simply the result of a greatly enhanced appetite?

SUMMARY

A controlled trial of aureomycin and chloramphenicol in the outpatient treatment of children with whooping cough has shown that both antibiotics are effective in reducing the cough count, but chloramphenicol also lessens the whooping and vomiting and loosens the cough

Children receiving aureomycin in powder form develop a voracious appetite

I am indebted to Dr W H Bradley for his continued interest, to Mr J A. Rouse for much help, and to the Lederle Laboratories Division, Cyanamid Products Ltd, for the supply of aureomycin used in this trial

When the s.s. *Mooltan* docked in London on Dec 15, 1949, with a total complement of 1012 crew and passengers, 3 members of the crew were removed to hospital with typhoid fever Ultimately 67 typhoid patients, of whom seemed to be carriers, were found, excretors, 10 were admitted to the Brook Hospital and 21 of these admitted on Dec 16, the twelfth day of illness, his symptoms having appeared between Port Said and Marseilles Later, patients were admitted at various periods, some as early as the third day of illness Of the 21 patients, 8 were British and 13 Asiatic

CONDITION ON ADMISSION

The cases were of typical typhoid fever with toxæmia, the majority experiencing headache, cough, and abdominal discomfort In most of the second week

† Case of cystitis two courses of ten and sixteen days

cases there was tenderness under the left costal margin though the spleen was not palpable Some diarrhoea was experienced by most of the patients Of these cases 6 were graded as mild, 7 as moderately severe, and 8 as severe

PROGRESS

There were no deaths, and complications were very few Convalescence was generally rapid and uneventful There was no evidence of any vascular thrombosis There were no cases of hæmorrhage or perforation One patient developed deeply eroded lingual and scrotal ulcers, which persisted for three or four weeks before healing, serological tests for syphilis were negative Another patient developed cystitis due to *Salmonella typhi* shortly after the first course of treatment, which led to two relapses and needed altogether three courses of chloramphenicol, the last course apparently finally cured the illness, and the urine and faeces became free from typhoid bacilli

TREATMENT

Treatment with chloramphenicol was started as soon as possible after admission, at times varying between the fourth and sixteenth day of disease Two types of therapy were used The first 6 patients were treated by a standard Woodward Smadel régime—i.e., 4 g as a loading dose followed by 3 g daily until twenty-four hours after disappearance of fever, and 1.5 g daily for five days afterwards The duration of treatment in each case is shown in the accompanying table After the first 6 patients had been admitted and treatment started, it was thought possible, after discussion with Dr W H Bradley, that a more intensive course for a shorter time might be effective, and it was decided that short intensive treatment, consisting of 4 g as a loading dose followed by 2 g six hourly up to a total of 20 g in forty-eight hours, should be given to what were considered the less severely ill patients, and the more orthodox régime given to the more severely ill The selection of cases for the two series was therefore not purely random Of the 10 patients who were intended to have only the short course of treatment 4 showed well marked symptomatic improvement at the end of the

first forty eight hours, but seemed not to be maintaining their improvement in the next forty eight hours, so treatment was continued on the general lines of the Woodward Smadel régime

The material therefore consists of 6 patients who had an intensive course for forty-eight hours only and 15 patients who had varying periods of treatment, from nine days upwards. The total dosage of chloramphenicol was 20-35 g

RESPONSE TO TREATMENT

Our results were similar to those already recorded by Smadel et al (1949), Woodward et al (1950), and others. There was a conspicuous general improvement both subjective and objective, in forty eight hours, and defervescence usually took place within four days. One patient, who required a heavy dose of 35 g in thirteen days, was not completely afebrile until the seventh day of treatment, and another patient developed a cystitis and recrudescence of pyrexia while still receiving chloramphenicol

TOXIC EFFECTS

No toxic effects were observed except internal ophthalmoplegia, which led to difficulty in vision and was reported in 4 of 10 patients who received the heavy dose of 20 g in forty eight hours. This incidence may be lower than the true figure, since many of the patients did not read and did not report minor symptoms owing to linguistic difficulties. The ophthalmoplegia was purely temporary and only lasted during the period of heavy dosage. Gray (1950) noted visual effects of chloramphenicol in the clinical treatment of pertussis and in normal volunteers, symptoms appeared to occur at a blood-chloramphenicol level of about 50 µg per ml. Ralston and Payne (1950) also noted eye symptoms during the treatment of brucellosis with chloramphenicol. Nausea and vomiting were conspicuously absent.

RELAPSES

As in all previous series treated with chloramphenicol, the relapse rate was very much higher than in any earlier typhoid series, it amounted to 12 out of our 21 (57%). A second relapse was noted only in 1 case—the patient with cystitis. Most of the relapses were severe, being characterised by a rapidly attained pyrexia up to 103°-104°F and by recrudescence of the toxæmia, malaise, &c., of the main attack. The recurrence of a bacteraemia was confirmed by blood culture in all relapses except one. The one exception was clinically typical and at the time when relapse might have been expected, but repeated

Fig. 1—Lack of correlation between relapse and length of treatment with chloramphenicol: hatched columns patients who did not relapse.

blood cultures were negative. This relapse and one other, which was not severe, did not receive specific treatment, and recovery took place in five and six days respectively. All the other relapses were severe and were treated with relatively long courses of chloramphenicol, to which they responded as the initial attack had done. All the cases of this series are summarised in the table, those which relapsed being separated from those which did not.

Relation of Relapse to Length of Treatment—Of the 6 cases treated for only forty eight hours 4 relapsed, whereas of the 15 treated for nine days or more, 8 relapsed. The difference in relapse rates of these two groups is not

Fig. 2—Time relation of relapses to end of treatment: stippled columns patients treated for nine days or more; hatched columns patients treated for only forty eight hours.

statistically significant. Fig. 1 shows the distribution of relapses against the length of initial treatment. The suggestion of Smadel et al (1949) that relapse is inversely related to the length of treatment, and their report that no relapse occurred among patients treated for longer than eight days, is not confirmed by our findings. In our series there seemed to be no correlation whatsoever.

Time of Relapse in Relation to Previous Treatment—Fig. 2 shows the date of onset of the relapses in relation to the cessation of previous treatment. Except for 2 cases, the relapses all occurred between ten and sixteen days after the cessation of therapy—which is approximately the normal incubation period of typhoid fever. The day of relapse seemed to have no relation to the period which had elapsed from the beginning of the illness.

BACTERIOLOGY

The organism concerned in this outbreak was grouped by Dr A. Felix, F.R.S., as belonging to phage type A. It was inactivated in vitro by a concentration of chloramphenicol 3 µg per ml. In accordance with previous experience of Woodward et al (1950) this sensitivity was maintained in organisms isolated from the blood, urine, and faeces, whether from the original illness, convalescence, or relapse. There was no evidence of development of resistance to chloramphenicol.

Blood culture was used to isolate typhoid bacilli from all the patients, but serial cultures following diagnosis were not carried out except to confirm relapses suspected clinically. Faecal and urinary cultures were carried out regularly.

Although the organisms disappeared from the blood very rapidly after the administration of chloramphenicol, the effect on faecal cultures and urinary cultures was far from consistent. On the whole, the organism tended to disappear from the faeces during the periods of high dosage but this was by no means constant and some patients continued to excrete typhoid bacilli even in the presence of very high blood levels of the drug. The onset of clinical relapse and positive blood culture was not always associated with a return of bacilli to the faeces if these had been absent previously. Woodward et al (1950) found relapses in 4 out of 5 patients who continued to excrete typhoid bacilli under treatment.

BLOOD LEVELS

Blood chloramphenicol levels were consistently estimated in the present series. The method used was inactivation of *Bact. pneumoniae* K3 as test organism. The strain used had a sensitivity of about 3 µg per ml. and was found suitable for the period when patients were having fairly large doses of chloramphenicol. When doses of 15 g a day or less were given this organism was not sensitive enough, and another strain (K41) with a sensitivity of about 0.5 µg per ml. would probably have been better.

We had considerable difficulty at the beginning in not appreciating that both these organisms are much inhibited not specifically by the sera of many ill patients, and this intrinsic bacteriostatic action, plus the effect of chloramphenicol, prevented the growth of ordinary inocula in serum dilutions up to 1/250 in some cases. This intrinsic bacteriostatic action is readily destroyed by inactivation for thirty minutes at 56°C and this should

always be done if any antibiotic is being tested against this type of organism

Chemical assays by the method of Glazko (1949) were also made in parallel with the biological methods. On the whole, the results were similar in the lower ranges. In the higher ranges the chemical estimation sometimes gave rather higher values than did the bacteriological. This may have been because the chemical method does not distinguish chloramphenicol from some of its inactive metabolic products.

The levels found in the patients on the orthodox Woodward Smadel treatment were similar to those already recorded by previous observers with the massive dosage of 20 g in forty eight hours the highest level reached was 150 µg per 100 ml by the bacteriological and 185 µg per 100 ml by the chemical method. This was in a small man, who weighed only 7 st., in most of the patients on this dosage, however, only about 75 µg per 100 ml was reached.

A rough correlation between the dose of chloramphenicol per kg of body weight and the blood chloramphenicol level was found, but there was a good deal of individual variation. In all the patients on either the massive dosage or the orthodox régime the levels attained indicated satisfactory absorption of chloramphenicol, but there was no obvious association between those levels and the clinical results. The levels we found in the blood while patients were having 15 g a day were, however, so low that we doubt whether the continuation of the ordinary course with this dosage had any therapeutic value.

SUGGESTIONS FOR FUTURE TREATMENT

Our results have shown no significant difference in the relapse rate between those treated for forty eight hours only and those treated for longer periods. Knight et al (1950) found that, though 3 patients treated for only sixty hours did not relapse, 4 out of 10 treated for longer periods did. They therefore suggest that, to avoid relapse, treatment should continue very much longer. Smadel, at the Royal Society of Tropical Medicine on Feb. 16, 1950, suggested tentatively that five days' treatment should be followed by five days' rest and then a further five days' treatment.

From our experience the rest period seems too short, and we therefore suggest that treatment should be considered on the following lines: initial treatment with chloramphenicol 3 g daily should be given until the patient is afebrile, then there should be ten days' rest, and this should be followed by a further course of 3 g daily for three days.

SUMMARY

21 cases of typhoid fever among passengers and crew of s.s. *Mooltan* were treated with chloramphenicol. In all of them the early result was satisfactory, but 12 of 21 cases relapsed, usually ten to sixteen days after cessation of therapy. There was no correlation between relapses and previous dosage or duration of treatment.

A modified scheme of dosage is suggested.

Our thanks are due to Dr M. T. Morgan, medical officer of health, Port of London, for the information he has so freely placed at our disposal, Dr J. C. Thompson, who made the biochemical estimations of chloramphenicol in the blood, and Mr B. S. Mansell and Mr J. E. S. Greenstreet who did the greater part of the technical work.

CHLORAMPHENICOL IN SUBACUTE BACTERIAL ENDOCARDITIS

MICHAEL CURTIN

M.D., B.Sc. N.U.L., M.R.C.P.I., D.P.H., D.C.H.
REGISTRAR, SHERIFF HILL INFECTIOUS DISEASES HOSPITAL,
GATESHEAD ON TYNE

The comprehensive antibacterial effect of chloramphenicol is demonstrated in the experiments of Gray (1950), who found that the upper respiratory tract becomes completely sterile during treatment with this antibiotic. Evidence of its wide therapeutic range is provided in the reports of its successful use in viral rickettsial, spirochaetal, and many bacterial infections. The following case suggests that chloramphenicol may also have a place in the treatment of subacute bacterial endocarditis, when *Strept. viridans* is the causal organism.

CASE RECORD

On Oct. 18, 1949, a woman aged 23, in the eighth month of pregnancy, was admitted for investigation to Sheriff Hill Infectious Diseases Hospital. She had noted the insidious onset some seven weeks previously, of generalised joint pains, lassitude, anorexia, and malaise. During the week before admission transient oedema of her ankles had developed.

On examination the patient was apathetic, looked ill and was poorly nourished. Her lips and conjunctivae were pallid, and her skin had a light brownish yellow tint. The fingers showed early clubbing. The pulse was of poor volume and tension. Her apex beat was diffuse, and a palpable thrill was present. Clinically the heart was enlarged. The first sound in the mitral area was obscured by a loud harsh murmur, which continued throughout systole and was widely conducted. The second sound in the pulmonary area was reduplicated. Although foetal heart sounds were clearly audible, uterine

Erythrocyte-sedimentation rates and blood-cultures during treatment.

enlargement was not consistent with the duration of pregnancy. Temperature 101.2°F, pulse rate 112 per min, blood pressure 95/75 mm Hg, erythrocyte sedimentation rate (E.S.R.) 38 mm in one hour and 82 mm in two hours (Westergren), Hb 66%. White cell count 9700 per c.mm. (polymorphs 80%, lymphocytes 18%, monocytes 2%).

During the patient's first week in hospital she had an irregular intermittent pyrexia ranging between 98.2° and 103.4°F and *Strept. viridans* was isolated from two separate blood cultures.

Treatment with Penicillin.—On Oct. 25, treatment with penicillin was begun, 100,000 units being given two hourly (12 mega units a day). The patient's temperature fell by 1° during the first forty eight hours of this treatment, and she remained afebrile for eleven days.

On Nov. 7 there was a sudden return of her pyrexia (101.2°F). Next day the E.S.R. was 47 mm in one hour and 98 mm in two hours and her temperature had risen to 101.8°F. On the 9th the dosage of penicillin was doubled to 200,000 units two hourly (24 mega units a day), whereupon the patient again became afebrile within forty eight hours. After an initial improvement the E.S.R. again deteriorated, but it subsequently progressed satisfactorily (see figure).

On Dec. 3, while still receiving penicillin the woman gave birth to a full term baby weighing 4½ lb., who survived for only four hours.

On Dec. 30 the patient had been afebrile for seven weeks. All blood cultures taken during treatment had been negative,

S.R. was 10 mm in one hour and 22 mm in two hours, her general condition had improved considerably. Accord-
on that date, penicillin was discontinued, after sixty five
continuous treatment
Subsequent Progress—On Jan 7, 1950, eight days after
penicillin therapy had ended, the patient had a transient rise
in temperature to 99.4°F. A blood culture taken on Jan 14 again
showed *Streptococcus viridans*. On Jan. 18 the E.S.R. had deteriorated to
22 mm in one hour, and 86 mm in two hours
Treatment with Chloramphenicol—It was decided to have
the patient infected with organisms tested for sensitivity to chloram-
phenicol, and it was found that chloramphenicol inhibited
growth in a dilution of at least 1 in 40,000. On Jan 23, after
her blood culture had grown *Streptococcus viridans*, a course of
chloramphenicol was begun, she was given 8 capsules (2 g)
in the first hour and then 2 capsules (0.5 g) four hourly for
the next two days (total 68 g). During treatment with chlor-
amphenicol blood cultures were done every three days and
they grew *Streptococcus viridans*. By the tenth day of this treatment
the E.S.R. had slowed to 5 mm in one hour and 8 mm in two
hours, and it did not again rise above this level
On March 15 it was noted that during the four weeks since
the end of the course of chloramphenicol the patient had
remained afebrile, her E.S.R. had been constantly well
within normal limits, and twice weekly blood cultures had
been reported negative for *Streptococcus viridans*. Her general
condition had greatly improved. She said she felt perfectly
well, and asked to be discharged from hospital to continue
her convalescence at home
Follow up—On April 19 the patient was readmitted for
examination. Her general condition was good, her skin had

a healthy colour, her appetite had returned, and she was
gaining weight. She was afebrile and her E.S.R. was 3 mm
in one hour and 7 mm in two hours. There was no anaemia
(red cells 5,070,000 per c.mm., Hb 103%, white cells 5100 per
c.mm.). There was clinical evidence of residual damage to
the mitral valve, and the cardiac shadow showed considerable
enlargement of the left auricle and ventricle, but there were
no signs of congestive failure

COMMENT

The *in vitro* sensitivity of the infecting organisms, the
rapid disappearance of *Streptococcus viridans* from the blood-
stream during treatment, and the corresponding rapid
improvement in the E.S.R. suggest that this patient was
benefited by the chloramphenicol

It is fallacious to generalise on the response of a single
case to a particular form of treatment, but it seems that
chloramphenicol is worthy of further trial in subacute
bacterial endocarditis, at least in *Streptococcus viridans* cases
which prove resistant to penicillin therapy

My thanks are due to Dr J. Grant, medical superintendent
who obtained permission from the Ministry of Health for the
use of chloramphenicol in this case for his help and criticism,
and to Dr R. Norton, director of the Public Health Labora-
tory, Blakelaw, Newcastle upon Tyne, who carried out all the
bacteriological investigations, including the chloramphenicol
sensitivity tests

Reviews of Books

Graduate Obstetrics and Gynaecology

F. J. BROWNE, M.D., D.Sc., F.R.C.S.E., F.R.C.O.G., emeritus
professor of obstetrics and gynaecology, University of
London, consulting obstetric surgeon, University
College Hospital, London. Butterworth 1950. Pp 501.
50s.

Professor Browne's book consists of material selected
in talks given to doctors specialising in obstetrics and
gynaecology. If this fact is appreciated the arrangement
will seem less surprising, and it will be understood that
it is not offering a complete textbook. The reputation
of his lectures has reached many and distant parts of the
world. He has written, as he has spoken, from a life's
experience, and because he has always been a conscientious
and accurate observer, the value of his statements is
great. The text is profusely illustrated with excellent
photographs and pen and ink drawings, each chapter
ends with a comprehensive bibliography to enable further
research and to be made, and a carefully compiled
index concludes the book.

Le système nerveux et pathologie rénale

CHARLES DE MUYLDER, agrégé de l'enseignement
supérieur, Université Catholique de Louvain, Paris
Masson 1950. Pp 148. Fr 600.

We are already indebted to Dr De Muylder for
his valuable studies of the renal innervation. In this book
he deals with the normal and the pathological kidney,
discusses our incomplete knowledge of renal histology,
which he has himself supplemented by embryological,
comparative anatomical, experimental, and pathological
studies.

The special relations of nervous tissue with the kidney are
discussed, more than an innervation in the ordinary sense
of that term. During development there is a mesodermal
contribution with latent nervous possibilities to the kidney
from the lumbar ganglionic crest. This contribution appears
to be most precise at the level of the macular segment of the
distal convoluted tubule and the epitheloid cells of the
juxtaglomerular apparatus are probably mesodermal in
origin. The nervous system provides the kidney with a
rich though essentially vascular innervation with numerous
terminal formations. Nerve cells are few, unmyelinated
fibres plentiful, myelinated fibres present but relatively rare.
In his view, the juxtaglomerular apparatus with its particu-
larly precise nervous contribution is probably the centre for

the regulation of the nephron circulation. He believes that
renal ischaemia in man must in most cases be nervous in origin,
producing hypertension, when prolonged through an endocrine
mechanism, but he finds it impossible to decide with cer-
tainly, at present, which particular cells are responsible for
the secretion.

The work must interest all nephrologists. It clears up
many hitherto contentious points, summarises certain
aspects of the literature, and stimulates thought.
However, those keeping track of investigations being
made in many places on the renal innervation will
realise that even this fine contribution cannot solve all
the problems. An international conference, at which
all the evidence can be presented and fully discussed, is
surely indicated. Meanwhile, Dr De Muylder's new
publication is welcome.

Clinical Applications of Suggestion and Hypnosis

WILLIAM T. HERON, Ph.D., professor of psychology,
University of Minnesota, Springfield. Charles C. Thomas
London. Blackwell Scientific Publications 1950.
Pp 110. 22s. 6d.

SINCE the heyday of hypnosis, at the turn of the
century, little has been added to our knowledge of its
indications and limitations. Thus the monographs of
Moll and of Forel, both published in 1889, give practically
the same information as the numerous recent works. In
either case the theories advanced to explain its effects
are far from plausible, and hypnosis remains a mystery
which has resisted persistent and intelligent attempts to
discover its true nature. While its place in psychotherapy
is now regarded as rather limited, the experience gained
in learning to hypnotise is of great value in the training
of psychotherapists, whatever methods they may later
employ. It is reasonable to suggest, too, that a back-
ground knowledge of the technique can assist the anaes-
thetist in his approach to some kinds of patient, however
mechanised his art has now become.

In hypnotising the first few cases everything depends on a
sound technique and a suitable attitude to the task. Professor
Heron's lucid manual is full of really practical help. The book
is addressed to the professional reader, with a proper respect
for the dangers of the method in untrained hands. The
author's proposals for the use of hypnosis and suggestion in
dentistry will be of interest to any dental surgeons not
influenced by the time factor, and the instructions given are
easy to follow. The idea of getting the edentulous patient
under hypnosis to imagine himself at the age when he had
sound teeth and to shut his mouth and hold it as he did then,

always be done if any antibiotic is being tested against this type of organism

Chemical assays by the method of Glazko (1949) were also made in parallel with the biological methods. On the whole, the results were similar in the lower ranges. In the higher ranges the chemical estimation sometimes gave rather higher values than did the bacteriological. This may have been because the chemical method does not distinguish chloramphenicol from some of its inactive metabolic products.

The levels found in the patients on the orthodox Woodward Smadel treatment were similar to those already recorded by previous observers with the massive dosage of 20 g in forty eight hours the highest level reached was 150 µg per 100 ml by the bacteriological and 185 µg per 100 ml by the chemical method. This was in a small man, who weighed only 7 st, in most of the patients on this dosage, however, only about 75 µg per 100 ml was reached.

A rough correlation between the dose of chloramphenicol per kg of body weight and the blood chloramphenicol level was found, but there was a good deal of individual variation. In all the patients on either the massive dosage or the orthodox régime the levels attained indicated satisfactory absorption of chloramphenicol, but there was no obvious association between those levels and the clinical results. The levels we found in the blood while patients were having 1.5 g a day were, however, so low that we doubt whether the continuation of the ordinary course with this dosage had any therapeutic value.

SUGGESTIONS FOR FUTURE TREATMENT

Our results have shown no significant difference in the relapse rate between those treated for forty eight hours only and those treated for longer periods. Knight et al (1950) found that, though 3 patients treated for only sixty hours did not relapse, 4 out of 10 treated for longer periods did. They therefore suggest that, to avoid relapse, treatment should continue very much longer. Smadel, at the Royal Society of Tropical Medicine on Feb 16, 1950, suggested tentatively that five days' treatment should be followed by five days' rest and then a further five days' treatment.

From our experience the rest period seems too short, and we therefore suggest that treatment should be considered on the following lines: initial treatment with chloramphenicol 3 g daily should be given until the patient is afebrile, then there should be ten days' rest, and this should be followed by a further course of 3 g daily for three days.

SUMMARY

21 cases of typhoid fever among passengers and crew of s.s. *Mooltan* were treated with chloramphenicol. In all of them the early result was satisfactory, but 12 of 21 cases relapsed, usually ten to sixteen days after cessation of therapy. There was no correlation between relapses and previous dosage or duration of treatment.

A modified scheme of dosage is suggested.

Our thanks are due to Dr M T Morgan, medical officer of health, Port of London, for the information he has so freely placed at our disposal, to Dr J C Thompson, who made the biochemical estimations of chloramphenicol in the blood, and Mr B S Mansell and Mr J E S Greenstreet who did the greater part of the technical work.

CHLORAMPHENICOL IN SUBACUTE BACTERIAL ENDOCARDITIS

MICHAEL CURTIN

M.D., B.Sc. NUI, M.R.C.P.I. D.P.H., D.Ch.
REGISTRAR, SHERIFF HILL INFECTIOUS DISEASES HOSPITAL,
GATESHEAD ON TYNE

THE comprehensive antibacterial effect of chloramphenicol is demonstrated in the experiments of Gray (1950), who found that the upper respiratory tract becomes completely sterile during treatment with this antibiotic. Evidence of its wide therapeutic range is provided in the reports of its successful use in viral rickettsial, spirochætal, and many bacterial infections. The following case suggests that chloramphenicol may also have a place in the treatment of subacute bacterial endocarditis, when *Strep viridans* is the causal organism.

CASE RECORD

On Oct 18, 1949, a woman aged 23 in the eighth month of pregnancy, was admitted for investigation to Sheriff Hill Infectious Diseases Hospital. She had noted the insidious onset some seven weeks previously, of generalised joint pains, lassitude, anorexia, and malaise. During the week before admission transient oedema of her ankles had developed.

On examination the patient was apathetic, looked ill and was poorly nourished. Her lips and conjunctivæ were pallid and her skin had a light brownish yellow tint. The fingers showed early clubbing. The pulse was of poor volume and tension. Her apex beat was diffuse, and a palpable thrill was present. Clinically the heart was enlarged. The first sound in the mitral area was obscured by a loud harsh murmur which continued throughout systole and was widely conducted. The second sound in the pulmonary area was reduplicated. Although fetal heart sounds were clearly audible, uterine

Erythrocyte-sedimentation rates and blood-cultures during treatment

enlargement was not consistent with the duration of pregnancy. Temperature 101.2°F, pulse rate 112 per min, blood pressure 95/75 mm Hg, erythrocyte sedimentation rate (E.S.R.) 38 mm in one hour and 82 mm in two hours (Westergren), Hb 66%. White cell count 9700 per c mm (polymorphs 80%, lymphocytes 18%, monocytes 2%).

During the patient's first week in hospital she had an irregular intermittent pyrexia, ranging between 98.2° and 103.4°F and *Strep viridans* was isolated from two separate blood cultures.

Treatment with Penicillin.—On Oct 25, treatment with penicillin was begun, 100,000 units being given two hourly (1.2 mega units a day). The patient's temperature fell by 1°F during the first forty eight hours of this treatment, and she remained afebrile for eleven days.

On Nov 7 there was a sudden return of her pyrexia (101.2°F). Next day the E.S.R. was 47 mm in one hour and 98 mm in two hours, and her temperature had risen to 101.8°F. On the 9th the dosage of penicillin was doubled to 200,000 units two hourly (2.4 mega units a day) whereupon the patient again became afebrile within forty-eight hours. After an initial improvement the E.S.R. again deteriorated but it subsequently progressed satisfactorily (see figure).

On Dec 3, while still receiving penicillin, the woman gave birth to a full term baby weighing 4½ lb, who survived for only four hours.

On Dec 30 the patient had been afebrile for seven weeks. All blood cultures taken during treatment had been negative,

THE LANCET

LONDON SATURDAY, DEC 16, 1950

Liquefaction of Exudates

IN the old pre-antibiotic days the clinician treating empyema had to depend on the formation of fibrinous and later fibrous adhesions between visceral and parietal pleura to obliterate the abscess cavity and extirpate the infection. This was achieved only at the cost of some permanent fibrosis with impairment of lung movement. The advent of effective anti-bacterial agents has profoundly changed the outlook. Now that the infection can readily be controlled with penicillin or some other agent the deposition of fibrin is an actual disadvantage, not only because of the late effects of fibrosis but because the drug cannot make contact with bacteria enmeshed in a fibrinous network. That is why various methods are being tried to combat the formerly essential process.

One method, already reviewed in these columns,¹ is that of TILLET and colleagues,² using two enzymes produced by hæmolytic streptococci of group A and some other groups. These are streptokinase, or SK, which reacts with globulin in plasma or exudate to become actively fibrinolytic, and streptodornase, or SD, a deoxyribonuclease able to liquefy the stringy fibrils of nucleoprotein, derived from dead leucocytes, that are largely responsible for the viscosity of pus. The effects of injecting these enzymes into the pleural cavity have been studied by JOHNSON,³ who has demonstrated that they can cause the disappearance of extracellular deoxyribonucleic acid and degenerating cell nuclei from purulent exudates without interfering with the activities of living leucocytes. He ascribes the clumping of leucocytes in pus to their being caught in a matrix of nucleoprotein, since the clumps disintegrate on the addition of deoxyribonuclease. SK has proved its value in major thoracic surgery by making large hæmatomas liquid enough to be aspirated, and SD's assistance in the sterilisation and aspiration of abscesses has also been borne out in practice. The two substances have been separated and purified by CHRISTENSEN's⁴ method, and their clinical uses are reviewed by BLATTNER.⁵ Their toxicity will depend on the purity of the preparations used and the type of lesion treated, in America, the intrapleural injections were followed by transient febrile reactions and only moderate degrees of malaise. At Great Ormond Street, CATHIE has used a somewhat cruder preparation of SK (presumably containing SD),⁶ mixed with streptomycin, for intrathecal injection in children with tuberculous meningitis. His preliminary results⁷ were encouraging, and in this

issue (p 784) he and Dr MACFARLANE bring their experience up to date. Altogether, since February, 1947, they have treated 60 cases. The 20 who formed their first series received streptomycin only, intramuscularly and intrathecally, and 5 (25%) of these are still alive, 4 with normal cerebrospinal fluid (C.S.F.). The remaining 40 cases were treated with intramuscular streptomycin and intrathecal injections of streptomycin plus SK, 34 of them also receiving intrathecal 'Sulphetrone', 23 (58%) of this second series of 40 have survived, 17 with normal C.S.F. Credit for the improved results is mainly given to the SK, and CATHIE and MACFARLANE are doubtful whether the addition of sulphetrone had any effect. In their routine course the intrathecal injections were limited to 24 spread over six weeks, but there were individual variations, depending on the response to treatment. They emphasise the importance of giving SK from the beginning, before the fibrin clot becomes organised. In Melbourne, WILLIAMS and BAZELEY⁸ have used a highly purified preparation of SK in much the same way. Their material has been given over long periods and in repeated courses without causing any obvious reaction in the theca. The clinical results are not dramatic—of the 9 cases treated, 3 seem likely to survive, compared with 5 of the 27 treated before the addition of enzyme was started—but nevertheless the method is thought to deserve further trial.

Last week (p 739) ARMSTRONG and WHITE reported their work on deoxyribonuclease obtained from ox pancreas. They explained the tendency for the deoxyribonucleic acid (or the nucleoprotein) to undergo polymersation and to take the form of fibrils or rods, and they showed that the viscosity of thick purulent sputum is due to these fibrils, which stain by the Feulgen method like cell nuclei. They described the isolation of the enzyme, D N-ase, from ox pancreas 10 kg of which yielded 2.5 g of dry enzyme. Large intravenous and intratracheal injections of D N-ase into rabbits caused no toxic symptoms, but later the rabbits' serum developed precipitins capable of inhibiting much of the enzymic activity. In vitro, the D N-ase activity was very high, and the fibrils in smears of sputum were liquefied leaving living leucocytes unchanged. The preparation was given as an inhalation spray to patients with purulent sputum, and it produced the expected liquefaction, the volume of sputum increasing at first and then lessening. Injections of the solution into an empyema cavity successfully liquefied the exudate. In its potency and freedom from toxicity this seems to be a preparation of great promise, and its cost should not be prohibitive.

With the same objects of liquefying purulent material and securing better contact between antibiotic and bacterium, GRACE and BRYSON⁹ in New York have for some years been advocating the addition of a detergent to solutions of penicillin in the local treatment of chronic osteomyelitis. Systemic penicillin is given at the same time. They insist that in such cases surgery should be limited at most to excision of the sinus track and drilling of the bone to permit the insertion of a T-tube into the marrow cavity. Thereafter a solution containing 10,000–20,000 units of penicillin per ml and 0.1% of a detergent is instilled down the tube four hourly for ten days or so. There

while the bite is adjusted, must be original, and Professor Heron is careful to point out that the success of the method is attested only by the reports of a number of dentists rather than by any scientific evidence

This book is a sound guide for anyone who wishes to learn to hypnotise or to improve his technique. The hypnotist is presented as the tutor of his patient rather than as a dramatic figure imposing his will on another, and the book is notably free from doubtful claims and speculations

Injuries to the Ankle

J GRANT BONNIN, M B Melb, F R C S, orthopaedic surgeon, Central Middlesex Hospital, London. London Heinemann Medical Books 1950 Pp 405 63s

BECAUSE Mr Bonnin evidently has a passionate interest in fractures and other injuries around the ankle-joint, and can communicate his enthusiasm, his book will interest every practising orthopaedic surgeon—though it may not appeal to less senior students. Enthusiasm has its drawbacks, however, and the lengthy expositions of the historical and experimental aspects of the subject and a somewhat over-zealous classification of injuries by their mechanism of production may tire the reader searching for practical advice. This is a pity, for sound surgical guidance in treatment is there in abundance, though embedded in other material. Mr Bonnin is an advocate of open operation, evoking the spirit of Lane but though it is clear that, in his hands, operative fixation of ankle fractures gives excellent results, the experience of others less skilful may prove less happy.

Despite the strains which in places it imposes on the reader, this book is likely to prove a success

A Clinical Pathology Application and Interpretation

BENJAMIN B WELLS, M D, P H D, professor of medicine, University of Arkansas. Philadelphia and London W B Saunders 1950 Pp 397 30s

THIS comparatively small book differs in approach from the standard works on the subject. "Beginning with a clinical situation, the applicable laboratory procedures are selected and their contributions to the problem are discussed with just enough theory and methodology to convey proper meaning and purpose." There are few illustrations and very few references are given, though it is apparent that many have been consulted. The scope is limited, but the book may help the clinician to choose and understand simple tests

An Introduction to Personality Study

RAYMOND B CATTELL, research professor in psychology, University of Illinois. London Hutchinson's University Library 1950 Pp 235 7s 6d

IN the more descriptive parts of this handbook Professor Cattell has drawn effectively on the writings of Freud and McDougall. He is less fortunate in his attempt to apply the statistical techniques of "factorial analysis" to his concepts of human personality. The book will be of value to undergraduate students of psychology, for it contains much material in summary and schematic form, and a number of useful comparisons are made between writers of different schools. It cannot be recommended as an introduction to the subject for those whose primary interests lie in other fields

A Pocket Obstetrics

(2nd ed.) ARTHUR C H BELL, F R C S, F R C O G, obstetric surgeon, Westminster Hospital, London. London J & A Churchill 1950 Pp 156 7s 6d

If time is short and knowledge weak
Synopsis series you may seek

This little work by Arthur Bell

May do the job and suit you well

(A book condensed but still complete,

May yet examiners defeat)

The text is brief and quickly told,

Advice is sound and dogma bold,

But do not, reader, be misled

For all our praise, it can't be said

That Bell's synopsis, be it good,

Replaces textbooks, never could!

British Encyclopædia of Medical Practice (2nd ed. London Butterworth Medical Publications 1950 Vol. 3 Pp 669 £3)—The new edition of this important work, edited by Lord Horder, is coming out at a spanking pace, the first three volumes have appeared in four months. The publishers can fairly claim that, with the annual cumulative supplement, the articles never fall greatly behind the times. Moreover, the supplement can readily be correlated with the main volumes, whose pages contain key numbers for cross-reference

Operations of General Surgery (2nd ed. Philadelphia and London W B Saunders 1949 Pp 890 67s 6d)—The second edition of this textbook by Prof Thomas G Orr, of Kansas, has had so many additions that it is almost a new book. Certainly it is much more useful to the general surgeon. It now contains descriptions of modern operations upon the lungs, œsophagus, and blood vessels, and everywhere are signs of extensive revision. Even greater help would have been given to the reader if more had been said about the difficulties and risks met in carrying out the instructions laid down. But as a bibliography is attached to each section, those interested can refer to original sources

Orthopaedic Surgery (4th ed. London Edward Arnold 1950 Pp 1016 50s)—This is the first new edition of Prof Walter Mercers textbook since the war, and marks almost two decades of continuous success with generations of students. The well revised volume now runs to over 1000 pages, but its comfortable personal style makes it easy reading. The thoughtful essays on cervical and lumbar intervertebral disc prolapse are notably sound, and it is gratifying to see the management of peripheral vascular disease retained in an orthopaedic textbook. The sections on osteomyelitis and infections of the hand perhaps have an over surgical approach to treatment, nowadays somewhat outmoded, and the importance of deciding between primary or delayed suture in osteomyelitis is not perhaps sufficiently stressed. But these are minor criticisms of an old favourite

Fortschritte der Tuberkuloseforschung (Basle Karger 1950 Pp 307 Sw fr 38)—To write a critical analysis of recent work, and review the subject lucidly and comprehensively in the light of such work, is never easy. Two articles in this volume are outstanding: that by G Canetti on tuberculous allergy, and a second by Canetti and G Roher on streptomycin resistance. They will be a valuable guide to workers who approach these subjects afresh, but also to those lost in the morass of accumulated literature. Each article in the volume is by an acknowledged authority in the particular field reviewed. Florence Seibert summarises progress in the chemistry of tuberculin. G Middlebrook writes on recent advances in bacteriologic research, K Diehl on congenital factors in tuberculosis, and H Good on the surgery of pulmonary tuberculosis. The editors, H Birkhäuser of Basle and H Bloch of New York, have performed a useful service. Two of the articles are in English, two in French and three in German

Metabolism and Function (Amsterdam Elsevier London Cleaver Hume Press 1950 Pp 348 57s 6d)—This book, edited by Dr D Nachmansohn and described as a collection of papers dedicated to Otto Meyerhof on his 65th birthday, is an attractively bound reissue of the first 348 pages of *Biochimica et Biophysica Acta* (1950, vol. 4). Such unity as it has derives from the fact that the contributors are past or present co-workers of Meyerhof's, or have been stimulated by the work of this versatile man. However, Meyerhof's own interests are so wide that there is as much variety in this volume as might be expected in a normal issue of the journal. The first section on Muscle, includes 7 papers, then follow 6 on Nerve and 3 on Drug Action, and the fourth section headed Intermediate Metabolism, contains 22 contributions on various aspects of animal, plant and microbiological chemistry. The more general articles include A V Hill's Challenge to Biochemists, with which the section on muscle opens and von Muralt's interpretation of the development of muscle chemistry as a lesson in neurophysiology. Nachmansohn has contributed an interesting paper on the relation of permeability to axonal conduction and synaptic transmission, arguing that acetylcholine is concerned primarily in the former. Wald writes of the interconversion of retenes and vitamins A. Krobs has sought to correlate tissue metabolism with body size in a range of animals from mouse to horse and incidentally includes a useful table of what is known of the composition of human plasma

for Reconstruction and Development, or governments outside the area. Indeed it is proper to describe the report as a prospectus advertising for subscribers to this £839 million loan. But the prospectus is peculiar in that there is no promise of financial dividends. In fact, the word dividend does not appear in the report, and obviously the returns will not be measurable only in rupees, pounds, or dollars, but mostly in more abstract assets. The final sentence in the report is "In a world racked by schism and confusion it is doubtful whether free men can long afford to leave undeveloped and imprisoned in poverty the human resources of the countries of South and South East Asia, which could help so greatly, not only to restore the world's prosperity, but also to redress its confusion and enrich the lives of all men everywhere." In all the great problems of South East Asia, economic factors, moral values, and the state of the public health are intimately interwoven. The Colombo plan calls on men and women throughout the British Commonwealth and in Europe and the Americas for financial sacrifices in order to "enrich the lives of all men everywhere." This is a noble aim; the evidence submitted suggests that it can be attained by full application of new scientific knowledge, provided this is not hampered by too much old-fashioned human wickedness.

The Tuberculosis Service

"The inadequacy of the present provision for the diagnosis, treatment and aftercare of tuberculosis is a national scandal."

WITH this round shot the Tuberculosis and Diseases of the Chest Group Committee of the British Medical Association open a report, recently approved by the B.M.A. Council, on tuberculosis and the National Health Service. At the end of last year there were 11,000 patients awaiting admission to the 23,000 beds provided for treatment, and there is no reason to suppose that the situation has since changed spectacularly for the better, though the Minister of Health recently stated that the general hospitals have now been responsible for "a very large increase in the number of beds." Though mortality from the disease continues to fall, contacts multiply, and notifications are rising. The Ministry of Health, the committee believe, clearly intend that the existing tuberculosis arrangements should be expanded into a branch of medicine dealing with all diseases of the chest, but this plan has been handicapped so far by the segregation of the tuberculosis service from other medical services. The chest clinic, the committee rightly insist, must be linked with the hospital. Again, prevention, social welfare, and aftercare of tuberculous families, though they are the responsibility of the local authorities, are duties which the committee find inseparable from the work of the chest physician. He should undertake them on behalf of the local authority, working as a consultant in close collaboration with the medical officer of health.

The chest clinics will have to be built up from the present dispensary service, and "many tuberculosis dispensaries, especially those which are part-time, have no X-ray equipment, no access to the basic services of a general hospital, and are inadequately housed in converted dwelling houses, local govern-

ment offices, and the like." Unequipped visiting stations of this kind, the committee think, should be retained only for special purposes—e.g., for interviewing in rural areas. Chest clinics proper should be associated with general hospitals, and established in some sanatoria. Large full-time chest clinics, with a permanent specially trained auxiliary staff, already exist in some hospitals. The committee suggest that the establishment of part-time chest clinics in smaller hospitals may upgrade such hospitals and enable them to offer specialist services previously available only at distant larger hospitals. They do not mention the cost of such upgrading of hospitals, but it must be borne in mind that all expenses incurred to improve care of the tuberculous must be saved from the cost of other activities in the health service. It is right and necessary that such concessions should be made to a body of patients whose need is so great, but it is unlikely that those working in other branches of medicine will hurry forward with proposals for reducing their own outlay. The responsibility for redistributing funds so as to allow of the expansion of the tuberculosis service lies fairly and squarely on the regional hospital boards.

The committee judge that in an urban area the optimum size of population to be served by a chest clinic is 200,000; in country districts the number would be less. This estimate agrees with that made by the Scottish Joint Subcommittee¹ last July. Both bodies thought that in compact urban areas with good public transport it is better to have one central fully equipped clinic than a number of minor ones. Such a clinic, the B.M.A. committee find, will need to take at least 5000 radiographs a year, and this means there must be an X-ray department in the clinic itself. Consulting and treatment rooms should be equipped for fluoroscopy. Small part-time clinics should use the X-ray department of the hospital to which the clinic is attached, but the committee suggest that the radiologist should be willing to leave routine reporting on these films to the chest physician. A chest clinic serving a population of 200,000, they say, would need a consultant and two assistant chest physicians, with an appropriate staff of registrars, an almoner, 5 health visitors and clinic nurses, and 5 clerks. Apart from any wards for the treatment of tuberculosis in general hospitals, there should also be some beds for diagnosis and assessment, and where possible these should be associated with a thoracic surgery unit. Each chest physician should control some of these beds in a general hospital. The development of chest clinics in general hospitals should make it easier for chest physicians to collaborate with their other specialist colleagues, and particularly the thoracic surgeon. Such arrangements, though they would give the chest physician a much firmer footing in the hospital than he has at present, are hardly the equivalent of the chest units envisaged by the Scottish subcommittee as "designed to include both the hospital and dispensary aspects of the service, and served by a single integrated staff."

The B.M.A. committee put the bed requirements for pulmonary tuberculosis at 1 per 1000 population,

¹ Tuberculosis Service in Scotland. Report of a Subcommittee appointed jointly by the Central Consultants and Specialists Committee in Scotland, and the Tuberculosis Society of Scotland. *Brit. med. J.* 1950 II 61.

can be little doubt that the detergent assists in the disintegration of pus, blood-clot, and other debris, and its action may be like that of D N ase. The suggestion that it also assists the drug to penetrate deeper into infected bone and thus sterilise it is harder to support. The irritant action of the detergents is said sometimes to impede treatment, but further information on this point is needed. It would also be valuable to have a control series, operated on by the same hands and treated by the same technique but with streptomycin (to control resistant bacteria) instead of the detergent. Without some such controls the part played by the detergent must remain uncertain, which is unfortunate since it would presumably be the cheapest of the liquefying agents.

Finally, there is a summarised report¹⁰ from New York on the use of highly purified crystalline trypsin, prepared in the Armour Laboratories. Dr REISER and his colleagues told the recent congress of the American College of Surgeons, according to the report, that they have washed out the cavity in tuberculous empyema with a solution of trypsin daily for seven to ten days, and that all pus, debris, and caseous material can then be aspirated, leaving the walls of the cavity clean and sterile. How many cases have been treated is not stated. An announcement from Armour Laboratories shows that the preparation is expected to be of value, like D N ase, in cleansing infected areas such as lacerated wounds, bronchi, and sinuses. In view of the well-known sequelæ of pancreatic fistula it seems remarkable that normal tissue escaped damage, but further reports will be awaited with interest.

These investigations, though still in their infancy, offer real hope of improvement in the methods for dealing with hæmatoma and local infection. Not only may they bring susceptible organisms and antibiotics better into contact, but the outpouring of fresh serum and leucocytes which follows the removal of stale exudate can be a valuable aid against some of the gram negative bacilli which are often resistant to antibiotics. But clinicians should remember that the enzymes mentioned are antigenic and may give rise to sensitisation. Moreover, as PARISH¹¹ points out, fibrin has its uses, and its removal in the immediate postoperative period might lead to hæmorrhage or to leakage from a sutured viscus.

The Colombo Plan

"The Colombo Plan for Cooperative Economic Development in South and South East Asia,"¹² prepared by a Commonwealth consultative committee including representatives of the governments of Australia, Canada, Ceylon, India, New Zealand, Pakistan, and the United Kingdom, was presented to Parliament by the Chancellor of the Exchequer last month. It begins by summarising the present economic position of all the countries in the region, whether they belong to the Commonwealth or not. In general the great havoc wrought by the war has been made good, but no more. Thus in 1949 the production of rice, wheat, and sugar was approximately the same as before the war, for fats and oils, recovery is

also nearly complete. Rubber, petroleum, and tea production are well beyond what they were in 1939, but jute and cotton supplies show no signs of rising from low war-time levels. Pre war rates of production, however, cannot even maintain the low pre war standards of living and poor health records, for the population of this region grows at the rate of 20,000 persons a day. At this rate of increase, the present 570 million inhabitants of the area will have become 720 million by 1970, and if these new citizens of the world are to have a life worth living, the supplies both of foods and of other raw materials must be greatly raised. This demands the application of new scientific techniques, on a grand scale, to the age old problems.

The Colombo plan describes development schemes already drawn up in India, Pakistan, Ceylon, Malaya, and North Borneo, and discusses their finances. A capital investment of £1868 million is needed between 1951 and 1957. Of this sum, 32% is wanted for agricultural purposes, 34% for transport and communications, 16% for industry, fuel, and power, and 18% for social and health services. The schemes cover a wide variety of purposes, but the most important are some ten huge new river dams by means of which it is hoped to irrigate 13 million acres of land and increase electric generating capacity by 11 million kilowatts (67% of the total present capacity). These two figures give some conception of the potential wealth in these countries. For realising the schemes, not only capital but also expert knowledge is required, and a table lists the categories of 1300 technical experts who will have to be brought from overseas. The greatest shortage is of mechanical and water engineers, and the report lays stress on the importance of these experts for the future of our civilisation. Among a variety of specialists, the list includes 80 doctors. Most of these are needed to fill temporary appointments for one or two years, and clearly they will have to be men and women of established professional reputation. It is to be hoped that medical schools and hospitals in this country will enable members of their staffs to take up such temporary appointments without loss of prospects on return home. The scheme also involves sending many doctors, nurses, and social workers abroad for postgraduate training. Thus the Indian government's plan includes overseas training for more than 1100 medical workers, Pakistan hopes to be able to send 50 nurses abroad for two or three years each, and Ceylon plans to send out 30 doctors a year for postgraduate training. If Great Britain is to maintain her present position as a centre for such training at least a proportion of our teachers must be familiar with the social and economic background against which such students will be working when they go back to their homes.

Throughout the report there is emphasis on the necessity of the new ventures in order to promote health and combat disease. But the overwhelming practical consideration is, of course, finance. Of the £1868 million of capital, it is estimated that the countries themselves can subscribe no more than £783 million, sterling balances will provide a further £246 million, but the remaining £839 million must come from other sources. It is suggested that these may be either private investors, the International Bank

twelve years' experience has shown that the bulwarks of the law need strengthening here and there and that there are open loopholes not seen by those who framed it perhaps the most daring proposal, at a time when which north wind brings us fierce and Doric complaints of "Whitehall government," is that these sections of the Act shall be extended to Scotland. We hope that this device will be followed and that medical officers of health north of Hadrian's wall will find them as useful as do their colleagues here. But it is the suggested code of practice that is likely to have most effect in improving the hygiene of a trade in which bacterial contamination is only too easy.

Of 66,830 manufacturers, only just over 1% can be classified as large scale enterprises, and it is the general experience that these show a laudable ambition to produce goods of the best possible hygienic standard. The smaller firms—bakers, pie makers, and butchers—may equal the best of their larger competitors, but often, in fact, they fall behind. They lack staff with specialised skill, the equipment which obviates the handling of food, space to work, and above all, knowledge of what can and should be done to avoid infection of these vulnerable foods. We suspect too that the fear of a civil prosecution for damages following food borne infection lies less heavily upon them than upon those firms whose names are on every hoarding. The principal problem of the working party was therefore to suggest means of persuading and helping the smaller man to raise his hygienic standards.

Some unsatisfactory features of the trade lend themselves to legal control: premises must be licensed and reach standards of construction which can be defined, domestic animals must be excluded, employees must wear clean overalls. But these rules alone are unlikely to effect much, and it is evident that the risks of contamination of food arise mostly from poor supervision, slovenly habits, and sheer ignorance of what constitutes dirty practices. The problems are those of applied bacteriology, and no honest hygienist would care to draft regulations for universal application with the promise that their enforcement would end the contamination of meat products. But expert knowledge can suggest many improvements in existing custom, and we hope that persuasion and advice to a trade that is eager for self improvement may lessen what has been a serious risk to the public health. Mr. Badman will always be with us, but the law as it stands can be used to check the more grossly unsanitary practices, and, since good hygiene is likely to go with good flavour and attractive appearance, we can expect support from a public which is becoming increasingly particular in its choice. For years legal penalties have been employed in the attempt to enforce cleanliness in the production of milk, but many observers would agree that greater improvement has resulted from the reciprocal visiting of the National Agricultural Advisory Service and the refusal of the wholesalers to accept sour milk.

Some details in the report deserve further notice. The dangers of gelatin are rightly emphasised. Few things that we eat are better culture media for bacteria, pathogenic and otherwise, and at least one outbreak of staphylococcal food poisoning extending into several counties has been traced to this source. It can be sterilised by heat, but repeated boiling will spoil its "gelling" properties. Slow cooling of cooked food is recognised as dangerous, since a temperature likely to encourage bacterial multiplication may persist for many hours, and the trade might well promote the design of cheap and effective chilling plant for the small manufacturer and the communal kitchen. Perhaps the part of the report most interesting to doctors is an appendix detailing suggestions by the staff of the Birmingham Accident Hospital for the dressing of small wounds of the hands

of those engaged in this and similar trades where soiling and wetting of the hands is unavoidable. It seems worthy of trial among nurses and our own profession.¹³

And lastly we would direct the attention of the sociologist to the extraordinary variety of made up meat foods which tickle the national palate. Now, gentlemen, what do you choose? Asalet, faggots, haslet, haggis, hog's pudding, or polony?

RADIOIODINE TREATMENT OF BLADDER TUMOURS

PAPILLARY carcinomas of the bladder have been treated by many methods since Beer introduced diathermy treatment in 1911. Any one method may be effective in a particular type of lesion, for the bladder is pleomorphic in the tumours it produces and no single treatment is likely to suit them all.

A new form of radiation therapy by means of isotopes seems to be remarkably successful in patients with multiple small papillary carcinomas, sometimes called papillomatosis, provided the lesions are still confined to the mucosa and have not yet infiltrated the muscle layers. It is now believed that in this condition the mucosa is in a premalignant state and the multiple tumours are evidence of a multicentric origin. Any treatment, such as diathermy, that is directed against only the obvious manifestations of the disease will therefore be incomplete, and new tumours may be expected to follow. Intracavitary irradiation with an isotope entails the insertion of a thin walled rubber balloon into the bladder—in men through a perineal urethrostomy, in women per urethram—and subsequent filling of the balloon with a solution of the radioactive isotope (150–200 ml). With this degree of distension the bladder mucosa is stretched over the surface of the balloon, and a tumour will be pressed firmly against the source of irradiation. The most effective isotope has been radioiodine (Na^{131}) made by irradiating common salt or sodium iodide for a week in the atomic pile. Na^{131} has a relatively short half life, so that apparatus contaminated with it will be safe after a few days. During its disintegration this isotope emits gamma and beta rays, and the quantities used in treatment administer to the tumours a dose of gamma radiation comparable to that from 0.5 g of radium used in the same way. The mucosa of the bladder receives a high intensity homogeneous dose, but the intensity rapidly falls as the rays pass through the tissues, and the bladder muscle therefore receives a considerably smaller dose, while the extra vesical tissues are scarcely irradiated at all. The duration of treatment is only about three to four hours, during which the bladder mucosa receives about 3000 r in the form of gamma rays and a similar amount as beta rays. At the end of treatment the balloon is removed, and the patient is usually fit to return home within a week. Because of the minimal surgical interference this is a suitable treatment for the elderly and the frail. The rapid falling off in the strength of irradiation prevents undesirable reactions in the skin or rectum.

The late results of radioiodine treatment will not be known until a sufficient number of cases have been followed up, but of the 30 patients treated at the Royal Cancer Hospital¹⁴ in the last eighteen months there are already 17 who are tumour free, judging by cystoscopy and mucosal biopsy. Complications may arise from underdosage or overdosage. If the dose is too small tumour regression is incomplete or absent and a second insertion of isotope is necessary. Where the dose has been too large the patients develop severe frequency of micturition some four weeks later, and this may persist for several months even when the urine is sterile. In 2

which is somewhat lower than the Scottish estimate. The Scottish subcommittee thought that many of the beds required could be provided in hospitals for infectious diseases, but the B.M.A. committee hope rather for the provision of more beds in general hospitals, and for the reopening of more sanatorium beds. This last depends on better nursing recruitment. Well planned propaganda, they believe, would present tuberculosis as an urgent national problem, and the interest of nurses could be aroused by teaching them something of modern achievements in treatment. Student nurses should have the opportunity of working in approved sanatoria or chest hospitals as part of their training. Even more important are proposals that trained or untrained nurses suffering from tuberculosis should be thoroughly reabled, that living quarters and amenities for resident staff should be

of the highest order, and that there should be some form of effective representation of sanatorium nurses on the General Nursing Council.

Prevention, care, and aftercare, which are the responsibility of the local authorities, are inseparably linked with treatment, and though clearer division of duties by regulation is necessary, the chief need is collaboration between people. The things to be done, regardless of who is to do them, are close supervision of notifications, health education of the public, the development of assisted housing schemes, mass radiography, control of milk supplies, B.C.G. vaccination, examination of contacts, aftercare and help for the family, the provision of home helps, and reablement. There is plenty here to keep both the clinical and the public health teams fully occupied, and to get through it they must work well together.

Annotations

VAGARIES OF HERPES ZOSTER

HERPES ZOSTER characteristically affects the posterior root ganglia, but commonly the nervous system is more widely involved.¹ There may be mild localised leptomeningitis with lymphocytic infiltration, inflammatory changes in the posterior and anterior horns of grey matter at the level where the spinal ganglia are affected, or peripheral mononeuritis both in the sensory nerves distal to the ganglion and also in the corresponding anterior root. These changes may be reflected in mild meningeal irritation with an excess of lymphocytes in the cerebrospinal fluid and occasionally by a lower motor neurone palsy involving muscles supplied by the anterior roots corresponding to the affected posterior root ganglia.² This palsy is found most often with zoster in the 5th and 6th cervical segments, when weakness of the shoulder girdle muscles appears with, or a few days after, the herpetic eruption, but with a lower dorsal zoster the anterior abdominal muscles may be paralysed, while with zoster at the level of the 2nd and 3rd lumbar segments the quadriceps femoris is paralysed. As to the cranial nerves, herpes zoster oticus, or the Ramsay Hunt syndrome,³ is relatively common, here the vesicles are often in the external auditory meatus, sometimes spreading on to the pinna, and are accompanied by a peripheral facial palsy and possibly by labyrinthine disturbance. Ramsay Hunt ascribed the facial palsy to involvement of the geniculate ganglion by zoster, but he had no supporting pathological evidence, and Denny Brown,¹ in a detailed pathological study of a case, found no changes in the geniculate ganglion but patchy infiltration with lymphocytes throughout the course of the facial nerve—a motor mononeuritis such as may occur in spinal anterior roots. With ophthalmic zoster also, spread of the infection to neighbouring nerves is occasionally evident, there may be partial oculomotor palsy, while rarely unilateral optic atrophy is a complication. Unilateral paralysis of the palate, pharynx, and larynx⁴ may be an accompaniment of zoster vesicles on the posterior wall of the pharynx and larynx. Much less commonly, the central nervous system is extensively involved. Encephalitis⁵ has been reported, the herpetic rash preceding the onset of cerebral symptoms by some days or even weeks, and diffuse myelitis apparently due to zoster has been described.

The evidence that the viscera may be involved is not so clear. The best authenticated cases are

those with urinary symptoms. Oppenheim⁶ described transient paralysis of the bladder associated with sacral zoster, while Dubois⁷ reported a case with herpetic lesions on the left buttock associated with urinary frequency and dysuria and finally retention of urine, in which cystoscopy revealed typical vesicles on the left side of the base and on the left lateral wall of the bladder. Furthermore, cases in which the bladder was very probably involved have been recorded by Darget⁸ and by Chesterman.⁹ Zoster of the pleura seems the probable explanation of the clinical picture in Russell Braun's¹⁰ patient, in whom zoster affecting the 5th and 6th dorsal segments on the left side was accompanied by severe pain on breathing and a harsh pleural rub exactly under the area of the cutaneous eruption. That zoster may attack the abdominal viscera is less certain, but Ryle¹¹ suggested this possibility in a case of duodenal syndrome accompanying zoster in the distribution of the 3rd and 4th dorsal segments, and in the case described by a correspondent on p. 822 the colon may well have been involved though abdominal symptoms did not start until a month after the herpetic vesicles appeared. The probable explanation of visceral involvement is that the virus travels down the autonomic nerves supplying the viscera, as it is thought to travel down sensory nerves to the skin.

These accounts suggest that with obscure neurological disease, and particularly with unexplained localised lower motor neurone lesions, the possibility of zoster should be considered, the mode of onset investigated and search made for herpetic vesicles or their scars.

SAVELOYS ET AL.

OF 191 outbreaks of food poisoning in the years 1945-48 whose origin could be traced with some certainty almost half were due to made up or processed meat, the number due to fresh meat was negligible. The recently published report¹² of a working party set up by the Minister of Food to consider present practices in the manufactured meat trade and advise on possible improvements in hygiene is therefore timely, and it includes some suggestions of interest to the profession as a whole.

The proposals are divided into suggested amendments to the law and regulations and a 'code of practice' to be adopted voluntarily by the trade. Manufactures of this kind are regulated by sections 13 and 14 of the Food and Drugs Act, 1938, and it is not surprising that

PROVISION OF SPECIALIST SERVICES IN REMOTE AREAS

ROBERT F MACDONALD

M.D. Aberd., D.P.H.

ASSISTANT SENIOR ADMINISTRATIVE MEDICAL OFFICER,
WESTERN REGIONAL HOSPITAL BOARD, SCOTLAND

In Scotland, particularly in the West and in the North, there are many areas which, because of their remoteness or inaccessibility, present special problems in the provision of specialist services. Obviously, if the patient cannot go to the specialist, the specialist must go to the patient, and over the past decade this has been accepted as a guiding principle.

For some years before the introduction of the National Health Service, these areas—especially the North-West of the Scottish mainland, and the Western and Northern Islands—had specialist services provided by their local authorities and by the Highlands and Islands Medical Service. In some areas the service was already substantial, and in 1948 the over all picture was one of continuous development. Fresh ground was being broken, and existing specialist care was being augmented.

BACKGROUND AND BEGINNINGS

In these remote districts the local population has only within comparatively recent years become accustomed to turn to the general practitioner for the treatment of minor ailments. In the past, a boy might grow to manhood without having seen a doctor within the boundaries of his native parish, unless there had been some disaster such as an outbreak of cholera or of enteric fever. To this day much discretion is used before summoning medical aid.

The inter war years saw the gradual development, under the ægis of the Highlands and Islands Medical Service, of comprehensive general practitioner arrangements, and by 1939 no area was without regular medical help, though its provision might tax the endurance and resources of the general practitioner to the utmost. A visit to a patient was often an expedition to be planned carefully with due regard to local knowledge of weather and tides, and carried out by such varied transport as lifeboats, fishing vessels, and hill ponies. Many a good tale has been hidden between the lines of a statement of travelling expenses with such items as so many "horse," "foot," and "water" miles. If the problem of getting to a patient was formidable, that of getting back was sometimes insoluble at least immediately. A comprehensive medical service was no new term to these practitioners. I well recall one whose habit it was to make a microscopical examination of the cerebrospinal fluid before sending a patient with suspected meningitis to hospital. Most of them had to be, and in fact were, first-class general practitioners. Of necessity they were themselves the only medical specialists available to the remote areas.

In districts where small hospitals were set up the doctors in their vicinity were encouraged to become proficient in some specialty, and in many areas it became customary for one practitioner to undertake all the emergency surgery and also a good proportion of the cold surgery. The patient's own doctor usually gave the anaesthetic but here again was an opportunity for a general practitioner to gain recognition among his colleagues for special skill. Occasionally, a patient who was fit enough to travel would make the long and tedious journey by road, rail or sea to consult a specialist or to be admitted to one of the large city hospitals for investigation or operation. Less often, a specialist would journey to the patient, and perhaps operate in the

cottage hospital. Medical, surgical, or obstetrical emergencies were seldom moved to the large centres and most of them were treated by the general practitioner at the cottage hospital with the help of one or more of his colleagues.

BASIC APPOINTMENTS

The next step in the development of local specialist services was the appointment of a surgeon to strategically situated cottage hospitals. This specialist, who held a higher surgical qualification, lived in the area but did not engage in general practice. Besides undertaking all the emergency and general surgery of the neighbourhood, including orthopaedics and gynaecology, he was usually competent in the management of obstetrical emergencies, and often acted as medical consultant also. Anaesthetics continued to be administered by the general practitioners, and such in the main is the practice at present. The installation of small X ray sets made still further calls on the versatility of the local surgical specialist. Today many of these appointments cannot, and do not, provide full time work, but they are completely justified because the surgeon must be available at all times. He is an insurance against medical catastrophe.

In assessing the need for specialist services, it quickly became clear that a local appointment could be justified only for general surgery—and that only on grounds of emergency. Otherwise the population in any one area was not big enough to provide enough work for a whole-time specialist. On economic and professional grounds, therefore, all the other specialist services had to be organised on a part time or visiting basis.

The anaesthetic service presented peculiar difficulties. The appointment of a visiting specialist anaesthetist is seldom worth while, since much of the anaesthetics work is related to emergency surgery, which has to be carried out at remote places at short notice, and, consequently, most cases are undertaken by one or more general practitioners.

The basic problem was solved by appointing to a cottage hospital a competent surgeon, which gave a sense of security to practitioners and people alike. Free from the anxieties of general practice, he was able to give his whole time to his specialist responsibilities. Regular outpatient clinics were established at the hospital, operating theatre and ward fabrics were improved and equipment was provided. More nurses were recruited to deal with the increase in specialised work.

The amount of work a surgical specialist can do varies with the density of population in his area. Mere numbers are seldom a reliable index, for the ruling factor is always distance, and the sparser the population the more difficult it becomes to make the services of one specialist available to all. In Scotland, where travelling is often difficult, a surgical specialist in a remote area is seldom able to serve a population of more than 30,000, though he may have long intervals when by urban standards he is not hard pressed.

The next step in extending the services was the appointment of a part time general medical specialist who visited the area regularly and held outpatient clinics at the cottage hospital to which the general practitioners referred their patients. He was also available for consultation in the homes of patients who were unable to attend the clinic. How often he went was determined by a process of trial and error. Beginning at one session per month, the interval was lengthened or shortened according to the amount of work, which he came to be able, more or less, to estimate. Experience has shown that, for a population of 20,000, one whole day is required per month, exclusive of travelling time. Apart from acting as consultant, the visiting physician is a valuable link between the remote area and the larger centre at which his major appointment is naturally held. During his peripheral visits, arrangements are made for the

patients what seems to be a radionecrotic ulcer on previously healthy mucosa has appeared, both cases had an extremely large dose of irradiation by present standards. There have been no cases of urinary incontinence, and the perineal wound has always healed without delay.

A team of British workers, generously supplied with radioactive material by the atomic energy plant at Harwell, has been responsible for developing this original treatment. It will not be obtainable at every hospital, nor would this be desirable until we know more about the long term results, and it may be wiser if, for the present, experience is concentrated at the Royal Cancer Hospital. When used in correctly selected patients, it is clearly a valuable treatment in at least one form of bladder carcinomatosis.

HEADQUARTERS FOR POSTGRADUATE FEDERATION

London University is to buy from the Dominion Students' Hall Trust the freehold of a block of property in Bloomsbury, lying on the south side of Guilford Street, on which it is hoped ultimately to build the headquarters of the British Postgraduate Medical Federation. It is appropriate that the new site is near London House, where many of the residents are medical postgraduates from the Dominions.

ANTIBACTERIAL ACTION OF COD-LIVER OIL DISTILLATE

COD-LIVER oil is known to have a bacteriostatic action, and Solomides¹ has increased this considerably by distilling the oil at 250°C at atmospheric pressure and iodinating the product. The distillation is not a simple physical process, but is analogous to the "cracking" of petroleum, for the oil decomposes on boiling, some of the long chained and unsaturated fatty acids or their esters being broken down. The distillate consists of two fractions—the fatty acids, which inhibit the growth of pneumococci, streptococci, and some fungi, and the unsaponifiable fraction, which is germicidal and tuberculostatic. Iodination increases the germicidal activity of the distillate and makes it capable of lysing tubercle bacilli. Admixture with serum and body fluids does not affect its action on tubercle bacilli but weakens its germicidal action. Solomides has made the distillate injectable by means of emulsifying agents, such as Tween 80,² and the emulsified product is said to be practically non-toxic and not liable to cause local reactions. Solomides reports good results with local applications of the iodised distillate in 50 obstinate cases of eczema, and in patients with burns and mycoses, but he does not mention any control observations. The product's tuberculostatic action was confirmed in guinea-pigs, though the differences between treated and untreated animals was not spectacular. The dosage had to be judged very carefully, for the infected animals improved when treated with 0.01 g of emulsified iodised distillate daily for a month, but double this dose seemed to hasten their death from tuberculosis. The intradermal tuberculin test gave a negative or feebly positive result in tuberculous guinea-pigs which had been injected with 0.001 g of distillate daily for 3–4 weeks. Work on the same lines has now been reported by Emmerie and his colleagues,³ of Utrecht, who have found the unsaponifiable fraction strongly tuberculostatic *in vitro* but disappointing *in vivo* when tested in guinea-pigs. Solomides' clinical results with injections of the distillate in tuberculosis are not impressive. He does not mention the total number of patients treated, the radiological appearances, or the changes in erythrocyte sedimentation rate. Some

patients had a pyrexial reaction shortly after their injections and Solomides suggests that this arises from the liberated tuberculin of dead bacteria.

On the present evidence this cod liver oil distillate is of more academic than clinical interest. It has yet to be shown to have any beneficial effect in human tuberculosis, and the guinea-pig tests show that it is a double-edged weapon, but increasing the dose may exacerbate the infection. In local treatment it does not seem to have any advantages over the antibiotics.

CAT-SCRATCH AND TULARÆMIA

HUMAN infection with *Pasteurella septica* is now a recognised sequel to bites by cats and other animals which carry the organism in their mouth or respiratory tract. Such infections usually have a sudden onset with swelling and redness of the injured area followed by a benign course, but sometimes the inflammation persists a long time and osteomyelitis may be discovered after the initial lesion has healed.

Cats are thought to be the source of another infection, known in France as "la maladie des griffes de chat". Debré and his colleagues,¹ who have seen several cases, describe an example in a girl of six, who developed a small tender swelling in the groin without any other lesion in the limbs or perineal region. Despite treatment with penicillin the lump grew and the skin over it became discoloured and adherent. Aspiration produced pus, from which no organisms could be grown on the various culture media tried. The girl's Frei and tuberculin skin tests were negative, but an intradermal test with an antigen prepared from the pus of a similar case was strongly positive. The abscess discharged for some days but responded fairly rapidly to "Aureomycin". The child had no history or sign of claw marks, but she habitually played with cats at home. This case is typical of many seen recently in the country round Paris. The lesion is a subacute suppurative lymphadenitis involving one or several nodes and leading to an abscess which may reach 2–3 inches in diameter. There is little general reaction except for mild fever and sometimes a leucocytosis, though Weill and Lévy² have noted enlargement of the spleen in one case.

This condition seems to be distinct from the infections with *Past. septica*, but so far bacteriological and mycological examinations have not revealed its cause. Viral infection is a possibility, especially as cats and mice are often infected with viruses of the psittacosis lymphogranuloma group. Another explanation is put forward by de Lavergne and colleagues³ in their clinical review of the first epidemic of tularæmia in France. They point out that cat scratch infection resembles one of the varieties of tularæmia, and the skin test antigen prepared from cat scratch pus has produced a positive reaction in several proved cases of tularæmia. It is known that cats occasionally harbour *Past. tularæmiae*, but in the case reported by Dobró et al. the child's agglutination test for tularæmia was negative. Application of this test in other cases of cat scratch should quickly determine whether the two conditions are related.

CHRISTMAS

At a time when the rise of prices makes it harder and harder to make ends meet, the Christmas gifts which the Royal Medical Benevolent Fund sends to its beneficiaries are more welcome than ever. Contributions, marked Christmas Gifts, will still be gratefully received by the fund at 1, Balhol House, Manor Fields, London, S W 5.

population unit of 20,000 will justify one whole time radiographer and a regular monthly visit from a visiting radiologist. For radiotherapeutic services the remote area must look to the large centre, but a regular follow up and report clinic should be established in the periphery, where it would serve a most useful purpose.

The threshold of demand for a mental health service, certainly in the less obvious cases, is higher in these rural areas—possibly because of environment—than in the more populous centres. Few remote areas have enough work to justify a regular psychiatric service on a visiting basis. There is usually a well established liaison with a district or city mental hospital, but only too often this is regarded as merely the receiving hospital for certified cases. Domiciliary visits by psychiatrists wherever and whenever possible should be encouraged to promote closer contact between the mental hospital and the general practitioners.

Patients who need plastic surgery and neurosurgery should be referred to a central unit after screening by the local services. The work of the visiting physician will of necessity include pediatrics, cardiology, and possibly diseases of the chest, but he should be able to refer suitable cases to the appropriate central departments. Patients with venereal disease should be persuaded wherever possible to accept inpatient treatment at a central unit, returning later for continuing treatment by the general practitioner on a programme mapped out by the specialist.

Finally there must be available to general practitioners and visiting specialists a complete laboratory service including bacteriological, pathological, biochemical, blood transfusion and saline infusion facilities. Between the central laboratory and the peripheral area there should be a ready line of communication by post, telephone, and telegram.

CONCLUSIONS

At present the scope of specialist services in the North and West of Scotland varies considerably from area to area. In a few remote areas local facilities are still scanty and consist in little more than those afforded by the local surgical specialist, in others a fairly adequate service in the different specialties is offered. Such development is well worth while, for apart from its obvious advantages to the patients and practitioners of the area it will help to relieve the strain on over-crowded and overloaded outpatient departments in the larger centres.

In reviewing or planning the hospital services of a remote area, I would stress the importance of developing first and foremost local outpatient facilities within the small general hospital, even at the expense of local inpatient accommodation. Increased outpatient facilities, and an increase in the number of beds for the chronic sick and long term illness and tuberculous patients together with a full visiting specialist service, and an adequate number of beds at the appropriate central hospital units, should be the pattern of planning for the immediate future. There are many areas in Scotland, and no doubt areas in England and Wales, to which these principles could properly be applied.

good medical schools have developed the defects of the very virtues for which Flexner argued. He urged them to tie the scientific laboratory and the teaching clinic firmly into the structure of training. The laboratory sciences then too much subordinated to clinical teaching now stand too much alone. Their relation to clinical judgment is often left unclear in the student's mind. A good many young physicians have been taught to rely so confidently on laboratory diagnosis that when this fails there is nothing left to do for the patient. —Annual Report of the Commonwealth Fund 1950

HEALTH LEGISLATION IN AMERICA

FROM A CORRESPONDENT

American hospital authorities are apparently now in the same confused state of mind concerning health and hospital service as were hospital authorities in Britain immediately after the war. The latter, however, had to consider only two proposals, one providing for the coordination of the municipal and the voluntary hospitals, and the other for the complete transference of all hospitals to the Minister of Health. Moreover, these two proposals made their appearance at different times and were put forward by two different Governments. In America, reports *Hospitals* (July 1950), the official journal of the American Hospital Association, there are "nearly a dozen other proposals, each based on a different idea" to the original proposal for compulsory health insurance variously known as the Thomas Murray-Dingell Bill, the Wagner-Murray-Dingell Bill and sometimes as the Truman Bill, the Administration Bill, or the Ewing Bill, because of its support by the President and the Federal Security Administration. Some of the new proposals strive to avoid the criticisms made against compulsory health insurance, others are attempts to develop a basic principle into workable legislation.

OUTLINE OF BILLS

The latest Bill (HR 8746) was introduced as recently as June, 1950. It proposes to set up a Federal Health Reinsurance Corporation. By reinsuring the heavier losses for health insurance its proposer believes that it will be possible for local Blue Cross, Blue Shield, and other voluntary plans to give more attractive contracts to subscribers at a reasonable charge which, in the words of the proposer, "should cover the medical economic problem of the nation within a brief space of time without the necessity of bringing the government into the patient-doctor or patient-hospital relationship." The government's contact with the proposal would be confined to the local non-profit insurance associations. Initial financing of this plan would be by a \$50,000,000 Treasury appropriation in exchange for capital stock. Each eligible health insurance plan agreeing to participate would pay in premium charges 2% of the total gross payments received from subscribers. The corporation would pay two-thirds of each claim above \$1000 paid out by the plan for any period of 12 continuous months with respect to any individual subscriber. Prepayment plans would thus relax contract limitations and offer broader coverage, knowing that the government would assume financial responsibility for two thirds of the sum spent in excess of \$1000 in catastrophic cases.

S1679 is the original Wagner-Murray-Dingell compulsory health insurance bill. It provides for simultaneous enactment of a separate tax bill to levy a 3% payroll tax divided equally between employer and employee. The income from this tax would be put into a government trust fund. An additional 1% would be put in from the federal Treasury. This trust fund would be administered by a National Health Insurance Board of five persons, including the surgeon-general of the Public Health Service and the Commissioner for Social Security. The board would divide the trust fund among the States by mathematical formulae based on comparative need, cost of services and other factors, the allocation being in five main categories: (1) medical, (2) dental, (3) nursing, (4) hospital, and (5) auxiliary services such as pharmaceutical and radiological. The Bill makes no provision for indigent persons unless the local communities responsible for them pay premiums into the federal fund. An American authority remarks: "the cost of fulfilling this programme would be stupendous and probably far in excess of estimates, although the statistics of the Federal Security Agency aver that they are immune to the errors that have plagued the British in a similar venture."

admission of patients to the central hospital, usually to a unit under his care, for investigation and treatment beyond the scope of the outlying cottage hospital. This personal link does much to lessen for many patients the fear of the long journey to a large town and to a strange hospital, especially if, soon after admission, the patient sees again the doctor who was first consulted in more familiar surroundings. If at all possible, this sequence should not be broken. Between visits the general practitioners can make contact with the physician by telephone, and in emergency receive advice, or arrange for the immediate admission of a patient. Emergency visits can occasionally be paid to the area by the physician, but they are time consuming and transport is often difficult.

EXTENDING THE SERVICE

The appointment of a part time visiting obstetrician, gynaecologist, and the establishment of a combined antenatal, postnatal, and gynaecological clinic, was the next obvious gap to be filled. The obstetrician gynaecologist pays regular visits at about the same interval as those of the physician, and extraordinary visits are seldom practicable. Most emergencies can, however, be dealt with locally with the aid of the surgical specialist, or sent to the central hospital. Often they are foreseen by the specialist during his regular visits, and the patient is moved to hospital before danger arises.

The success of these services soon called for further developments. An orthopaedic service, for example, must now be regarded almost as an essential, and it

requires one visit or clinic session every two months per 20 000 of population. Here again, a sufficient number of beds must be reserved in a central orthopaedic unit to honour recommendations for inpatient treatment without undue waiting.

The chief difficulty of setting up an ophthalmological service has been the ever increasing volume of work. Intended primarily for children of school age, the service, again run on a visiting specialist and clinic basis, was soon called upon to cater for the preschool children and a rapidly expanding number of adults. For a population unit of 20,000, visits of two days per month, seem barely sufficient.

Perhaps an ear, nose, and throat service is the most difficult to establish. The appointment of a visiting otorhinolaryngologist helps only up to a point. Regular outpatient clinics and domiciliary consultations may be held, but, if the service is to be really successful, recommendations for further treatment must be carried out promptly and completely. Major emergencies can be dealt with locally or moved to hospital as in other specialties, but there is difficulty in providing the inpatient and often continuous outpatient treatment which is needed in this specialty. To consider one group of cases alone—children recommended by the specialist for removal of tonsils and adenoids—it is seldom practical to arrange for such large numbers to be admitted to the central hospital unit, and even if it were possible for the specialist to hold operative sessions locally, there are seldom enough beds at the cottage hospital. One possibility is to use empty beds in the local infectious diseases hospital. Special operations sessions held in these hospitals would soon reduce the waiting lists, and the work entailed would be helpful in maintaining the interest of the staff at times when they had few infectious patients.

Nearly all the small general hospitals serving these remote areas now possess an X ray plant. The equipment and, consequently, the service offered vary from the isolated X ray set, used only for the detection of fractures and dislocations, to the small modern and efficient X ray department run by a whole time radiologist and visited regularly by a radiologist. Efficient local X ray facilities are essential, and they must keep pace and be able to cope with the reasonable demands of the visiting specialists.

MEDICAL LEGISLATION IN NEW ZEALAND

FROM OUR NEW ZEALAND CORRESPONDENT

Two Acts of medical interest have been passed in the 1950 session

Medical Research Council Act, 1950—This incorporates the M.R.C., which has been in existence since 1937, in order to assure continuity of medical research and permanent conditions for research workers. It is hoped also to attract endowments and bequests to assist in medical research.

The membership is to include the director general of health, the permanent secretary of the Department of Scientific and Industrial Research, the dean of the medical faculty in the University of Otago, a series of nominees to be appointed by the minister from the B.M.A. board of health, N.Z. committee of the R.A.C.P. and R.A.C.S. and Royal Society of New Zealand, and two from the Senate of New Zealand University recommended by its academic board.

The functions of the council are to foster medical research, to publish reports, and to furnish advice. It may make grants to individuals, colleges and institutions from a fund to be vested in the council. Any discoveries made by officers of the council or by those working under its support are to be the property of the council.

These provisions mark a major step forward, and follow soon after the visit of Sir Henry Dale and others whose advice the government sought. During the discussion of the Bill in Parliament, strong representations were made on the importance of dental research. The minister (Mr J. T. Watts) announced that it was planned to appropriate £33,000 from government funds this year, as against £21,000 last year. This was in contrast to the total sum of £25-30 million spent last year in toto, on the health of the community.

Medical Practitioners Act, 1950—This consolidates previous Acts relating to registration and discipline, and adds a number of new conditions, chiefly those recommended by the Cleary report of 1948 on discipline under the Social Security Act.¹

The Medical Council remains much as before in constitution and powers, and becomes a higher court in relation to the disciplinary committee. It consists of seven members: the director general of health, the dean of the medical faculty, and five practitioners appointed by the minister, one on the recommendation of the B.M.A. Its powers are fine up to £100, suspension from practice up to twelve months with consent of the attorney general, and a motion to the Supreme Court to remove the practitioner's name from the Register. A new variety of registration is introduced (to be effective at a date to be gazetted)—conditional registration for recent graduates to be confirmed as registration after a period of internship or other service similar to that which is to be required in England. Reciprocity with other countries remains as before.

Within the profession discipline is vested in a Medical Practitioners Disciplinary Committee and in divisional disciplinary committees. All the members of these committees are medical men, and almost all are to be appointed by the B.M.A. Their scope is professional misconduct, short of grave impropriety or infamous conduct in a professional respect which is the concern of the Medical Council. The powers of the disciplinary committee are subject to appeal to the Medical Council, and include a fine up to £100, censure or order to pay costs and expenses.

Dietitians—Also passed in the 1950 session was a Bill to further the knowledge of nutrition and dietetics and to provide for the training and registration of dietitians under the Dietitians Board.

Qualification for registration is defined by regulations and power is given to the board to approve hospitals and other institutions as training schools. Registered dietitians are to have annual practising certificates and hospital boards may appoint only registered dietitians. The board has disciplinary powers over registered dietitians subject to appeal to a special magisterial board of appeal. The uniform and title of dietitian are protected under the Act.

¹ See *Lancet* 1949 ii 855

NATIONAL SERVICE FOR DOCTORS

THE Central Medical War Committee has been notified by the Ministry of Health that, with effect from Dec. 1, registered medical practitioners who are placed in grade III or grade IV by National Service medical boards, provided that they are considered suitable for employment in the Armed Forces, are to be regarded as available for National Service in the same way as doctors in grades I and II.

It is not at present proposed that this should be applied to doctors who were placed in grade III or grade IV before Dec. 1 and who may therefore have been officially informed that they were outside the field for call-up. Doctors graded III or IV by National Service medical boards on or after Dec. 1 cannot assume that they are unfit for National Service unless and until they are so notified by the Central Medical War Committee.

This change in the recruitment arrangements for doctors, which has been approved by the Central Medical War Committee, is necessary in view of the present shortage of medical officers in the Forces.

The Wider World

A VISIT TO GERMANY

FROM A MEDICAL CORRESPONDENT

A VISIT to Germany nowadays may be one of many things. A holiday of pre-war kind, with reservations and limitations, a visit to Oberammergau to see the Passion Play, or a visit either on business or politics or to the Occupation Forces or the Control Commission. It was to this last group that mine belonged: the Army and the Royal Air Force plus the Control Commission were my objectives.

Judging by my experience, the average speed of military vehicles on duty is round about 50 miles an hour. But the chief danger of such a visit lies in the overwhelming hospitality of all concerned, and the chief surprise (speaking broadly) is the good conditions in which members of the Occupation Forces live.

CHANGES AND DIFFERENCES

When, in 1945, I visited Germany for the first time after the war, the streets of Berlin were heaped with the debris of shattered buildings: the Chancellery was as easily accessible as the Nelson Column, and urns could still be picked out of the ruins. And while the black market flourished along the main boulevards, night life flourished in underground cellars. A gun (in the gangster sense) was flourished at my back as I talked with senior officers in the Press bar, and I saw two victims of casual shootings, both members of the Army.

That kind of thing has vanished, and, as far as the Services and the Control Commission are concerned, the background of life is more like that of an Indian station, in the days of British rule in India than anything else I know. But the work done in the Occupation Forces is just as hard as that of hard working men and women in this country, and the hours are often longer. Since 1945 this work has helped to change the whole scene. The food shortage once so acute has been overcome, hospitals are working, industries are working, long-distance trains are working and so are local train and tram services in the big towns. Nevertheless there is still unemployment, which is reflected in the ease with which domestic assistance is obtained.

Travelling in the British zone (which is about as big as England and Wales) one sees many differences between Germany and Great Britain, and some of them are unexpected. The countryside I saw was very well cultivated, but for the most part was in small fields

The Flanders Ives Bill (S1070) is patterned along the lines of the Health Insurance Plan of Greater New York, which hires its own staff physicians to care for its members and purchases hospital care on a group basis. Loans and grants would be provided to start such plans in communities and areas all over the nation, enrolment would be voluntary, and the premiums would be on the basis of a percentage of the family income. A national "yardstick" would be established, listing all the services that should be rendered by an ideal plan, and in each State the State agency and health council would establish a norm. This norm would indicate the cost of providing "yardstick" services in the State, and each community plan providing all the services listed in the national "yardstick" would be entitled to the State established norm for the services provided to each subscriber. If the subscriber's income were so low that his contributions, based on a percentage of his income did not reach the norm, the plan would receive a subsidy from State and federal funds. Opponents to this Bill say that it would be harder to administer than the compulsory health insurance Bill as, in both, doctors and hospitals would be under pressure to provide their services for prices beyond their control, and not every hospital would be able to provide its usual quality of care at the government-established norm. On the other hand proponents of the compulsory health insurance Bill believe this alternative to be the next best thing to their own Bill, one reason being that it requires a majority of the members of governing boards and community plans to be persons who do not furnish health services.

Another Bill (S1106), sponsored by Senator Lodge, proposes that the federal government should pay half the cost of State programmes to provide "certain medical services and medicines, which are standardised in their nature but which, because of their high costs, are not used in many cases in which their use is desirable." Medical aid would include radiological and laboratory diagnostic services, respirators, and drugs. The State would be required to participate financially, and the surgeon-general of the Public Health Service would allocate funds on the basis of demonstrated need. To those who believe that the distribution of health services can be solved by making health care less expensive, this bill has had considerable appeal.

Senator Hart, a dentist, sponsors Bill S2040. This is based on the belief that his professional colleagues must be more liberal in their approach to federal participation in the distribution of health services. His concept is a voluntary health-insurance plan operated by the federal government to pay all health-care expenses over \$5 a year for families with incomes under \$5000. Premiums and policies are to be established by a National Health Insurance Board of five members including the surgeon-general of the Public Health Service, who would represent the medical profession, representatives of hospital and dental associations, and two representatives of the general public. The entire responsibility for subscription charges, benefits, and administration would be handed over to this board. The Bill also proposes to establish a Department of Health, grouping under it all of the present health functions of the federal government.

The Taft Bill (S1581) proposes federal grants-in-aid to State devised programmes to make medical, dental, and hospital care available to persons unable to pay the whole cost. The Bill does not specify the method by which this could be achieved. In his own words Senator Taft says "I suppose my Bill would help a State programme of compulsory health insurance if the State wants it. But this is for the State to decide. The federal government should not impose an arbitrary pattern." The Bill offers general assistance (up to 25% of the cost of the State programme) for development of voluntary non-profit health insurance plans, establishment and staffing of diagnostic facilities and inducements to physicians and dentists to practise in low income areas.

S1450, the Hill Bill (known also as the Voluntary Health Insurance Bill), aims to encourage all self supporting

people to use voluntary health insurance, such as Blue Cross, for protection against the emergency cost of illness. It requires federal and State governments to permit payroll deductions for employees wishing to enrol in non-profit prepayment plans, and it would assist States in programmes to discover how the government might assist in extending voluntary health insurance rather than trying to undermine it. Persons unable to pay subscription charges for voluntary prepayment plans would be provided with unidentifiable cards or certificates which would entitle them to the same care as self supporting citizens. Claims in these cases would be identified only by contract number, and the cost of such care would be borne by the federally assisted State programme. The assistance aspect of the programme would be supervised by the government agencies, but the voluntary health insurance programme for the great majority of self supporting people would be left entirely free of regulations and would be stimulated to the fullest possible extent. This Bill also provides for (1) surveys of existing diagnostic facilities, (2) surveys of areas unable to attract doctors and dentists because of low income, (3) surveys of existing enrolment in voluntary prepayment plans, (4) payment of non-profit health insurance premiums during periods of unemployment, and (5) financing of long term care.

Under another compulsory health insurance Bill (HR6700), sponsored by Representative Mrs. Bosone, benefits would be payable on a "\$50 deductible" basis—that is, when a participating citizen has paid \$50 in medical care (including hospital care), or \$25 for dental care, the federal administration "shall pay the balance of the charges for services so furnished." The Bill would be financed by a 3% payroll tax on earnings up to \$3000 a year with an additional 1% from general tax funds as in S1070.

HR7418, sponsored by Representative Boggs is an ingenious scheme. It would modify the present federal income-tax law (which permits deductions of medical expense in excess of 5% of gross income to determine taxable income) as follows: if a taxpayer has a gross income under \$2000, he can deduct all of his medical expenses, for an income between \$2000 and \$4000 the deduction would be the excess over 1% of the gross income, from \$4000 to \$8000 it would be 2%, and from \$8000 to \$10,000 it would be 3%, from \$10,000 to \$10,000 the deduction would be the excess over 4% of the gross income, and over \$10,000 it would be 5%.

HR6819, sponsored by Representative Keating, is also concerned with income tax and medical expense but in a radically different way. If gross income is over \$2000, this Bill would permit 90% of health insurance subscription charges to be deducted from the tax itself. For income between \$2000 and \$4000 85% of the health insurance subscription charges would be deducted from the tax. For income between \$4000 and \$8000, the deduction would be 80% between \$8000 and \$10,000, 75%, and between \$10,000 and \$10,000, 70%. For incomes over \$10,000 the deduction would be 60%. The Bill would put the federal government in the position of paying a large portion of the health bill of the nation. Only approved health insurance subscription charges would be qualified, thus leading to some measure of federal control, and income tax would have to be increased to allow for the additional expense. A criticism of both HR7418 and HR6819 is that many of the citizens who most need relief on medical expense do not file income-tax returns.

The above are the major health proposals facing the present Congress. Some of them, it is pointed out in *Hospitals*, have a familiar ring about them, others are recent and the point is made that this is encouraging as indicating that legislators are not becoming stagnant in their thinking. The change seems to reflect a growing optimism—a reaffirmation of faith in the voluntary system. It is no longer a question of "compulsory health or nothing." Rather is it a choice of several methods and a seeking for workable schemes.

Disabilities

56 CEREBRAL PALSY

My problem is to behave normally, being equipped with arms and legs which move in any direction I choose, but which are likely to move in a series of jerks and also to move themselves when I am only to sit still. Recently the condition has been described to me as athetoid quadriplegia, but in my childhood no definite diagnosis was made and no treatment prescribed except for a brief course of massage in my third year.

My first attempts at solving the problem were not made with any conscious effort, although probably they were much influenced by my mother's guidance. I began to walk with my feet wide apart just before I was two. Though very liable to fall over, I was in a position to investigate life. I followed my mother about the house, and like every other child I began to learn by imitation and repetition. I would stress repetition. I knew perfectly well what I aimed to do, and I was convinced that if I tried often enough I should succeed. Fortunately that initial confidence has never left me.

I had seen my mother sewing and demanded a needle and thread for myself. She did not care to entrust a needle to my unsteady hands but gave me a bodkin. I regarded this as an unworthy tool. Having watched me with it, my mother decided that I was not, after all, likely to damage myself much, so I got a needle, and a pair of scissors as well. My cutting might be jagged, but I almost always accomplished the movement I intended, however waywardly. Even if I did lose control of a movement I was able to stop and so save myself from harm. It seems to me that severe accidents are more likely to befall normal people, who naturally neglect the one in a hundred chance, than those with cerebral palsy, who have their greater risk constantly in mind. In twenty eight years I have cut, burnt, and scalded myself but neither more often nor more seriously than a normal person.

I succeeded in sewing and in knitting by keeping my knees together, to give a firm base for operations, and resting my hands on them. Similarly, I typed and played the piano by dint of keeping the edge of my palm and my wrist on the frame of the typewriter or the border of the keyboard. If my hands rest somewhere I can use my fingers easily, but if I hold up both hands in front of me—the normal posture in sewing—I cannot make a movement of any accuracy. An improved action has often meant a more normal looking movement and posture, but unfortunately it has sometimes also meant increased muscular tension. Tension did in fact increase to the point where I remained comparatively still when not attempting to move and not embarrassed or under strain. Thus, when first made to relax, I was surprised by the extent of my involuntary motion in repose.

My mother soon realised that I must learn to meet people and transact naturally the day to day business of life. In early childhood my speech was hardly intelligible to strangers, but as soon as it improved a little she forcibly broke herself of the habit of answering for me and I had to make polite conversation to our various acquaintances. I was also sent into shops to ask for this or that with my mother remaining doggedly beyond call.

I have often wondered in retrospect at my mother's self control in letting me experiment slowly and clumsily with this and that when her impulse must have been to do these things herself quickly and safely. To that restraint I owe incalculably much. By the time I was four I was walking rather more steadily and was taking part in mild rough and tumble with other children. From imitating my mother I passed to imitating them, older and younger children might now and then look askance at me, but I was always at ease with my contemporaries

who accepted me with as little question as they did the rest of their environment. Gradually I walked with my feet closer together, and I remember walks punctuated by my mother's injunction to keep my knees back, for they tended to be slightly bent. For some years my head shook noticeably as I walked, but latterly that has subsided. I have been shown that my leg muscles are stiffer than they should be, and I try now to correct this tension, but walking causes me neither fatigue nor embarrassment. I can cover as much as fifteen miles in a day without discomfort.

At six years old I went to a small preparatory school, its chief virtue was in having few rough boys whose boisterousness might upset my precarious balance. Here I met for the first time one of my most stubborn problems—how to control my hand enough to write. When, at the age of nine, I went to a secondary school I could only write standing up and very slowly. Using a pen brought me almost to a standstill, so I wrote my entry papers in pencil. My admission probably determined all my subsequent life. Once and for all I was in the main stream, without time or inclination to regard myself as one apart. One or two of the staff tried to kill me with kindness, but the majority merely saw that I had reasonable ability and were anxious that I should make the best possible use of it. I was excused nothing except games and apparatus work in the gymnasium. Looking back, I am a little surprised by my own docility. One of the trials of my life was a weekly slip test—one word answers to grammatical questions written on a slip of paper some two by seven inches which I found most difficult to anchor and write on at the same time. It never occurred to me to ask for a larger sheet. There was also my history notebook in which, as a weekend task, rough notes were transcribed with all the niceties of indentation and red ink underlinings. To compass half without blot or smudge was to increase the agony of concentration lest I should mar the rest. All of this was done standing up. If I sat down and bent my elbow, I lost control of my hand. I wrote virtually with my whole arm. I realise now that trying to attain the accuracy and neatness expected of the average child greatly added to the tension in my muscles. However, for the mental discipline of those years I shall always be grateful.

When the rest were due to take school certificate I was asked if I wanted to enter. I answered Yes, and permission was obtained for me to write in indelible pencil; any time concession was, I learnt, out of the question. The examination was a race between me and the clock, my only hope was to start writing the moment I had read the question. In the event I had a "credit" for each of the seven subjects I had taken. Throughout the rest of my school career "credit" standard was usually the limit of my achievement, dependent as it was on the speed of my writing. After taking school certificate I resolved to write no longer standing up. I made myself sit down and found that by thrusting my left hand beneath my right I could control my hand, even though I had a permanent bruise through my fore arm rubbing against the edge of the desk. It was not better than standing up, but it looked better.

At eighteen I left home for the first time and went to college. I had mastered two or three years earlier the last item of my toilet—waist long hair to be brushed, plaited, and coiled. Other girls were more than willing to do the few things I could not, such as carrying buffet meals to table. Even now to be quite sure of not spilling from a cup, I either lift it with both hands or, less conspicuously, grip my right wrist with my left hand. For me, as for most undergraduates, academic work was only a part of life. I danced—not very well, I admit—had a hand in the college magazine, and debated. The days of indistinct speech were behind me, and I did not have

separated by stakes and strands of wire. The fields were as a rule so small as to make the use of most agricultural machines impossible and probably in any case uneconomic. The peasant with his hand hoe dominated the scene—sometimes a man and sometimes a woman. Very many chickens and geese were to be seen, and I was told that the poultry population was greater than it had been before the war. But during all my drives, including long distances on the autobahns, I only once saw an agricultural machine, and that was an early-model reaper and binder.

Another aspect of German farming which impinges directly on health is dairying. Cows are milked in the fields by the probably honest, but apparently usually unwashed, hands of the peasant, and the proportion of tuberculous cows is very high indeed. (For this reason no German milk is issued to British personnel, who get their milk out of tins *) On the other hand, statements that the incidence of tuberculosis is very high in the German population are not supported by the death rates, which do not correspond (our authorities found) with the alleged prevalence. A possible explanation lies in the fact that during the food shortage after the Armistice tuberculous patients, and presumably suspects, were entitled to higher rations. As ration scales went up, the apparent incidence of tuberculosis has gone down. Changed economic conditions have also worked other health changes. In 1946, at the time of the black market boom, when German currency was of very little value, the incidence of venereal diseases was very high. But this desperate state of affairs has passed. The cigarette is no longer a form of currency, and has got back to its pre-war position in the slot machine—a device which, some readers may remember, used to operate at reasonable prices in our own country.

THE MEDICAL PROFESSION

The organisation of doctors in Germany is on a basis of provinces (*Länder*). In the British zone there are three of these provinces—Schleswig Holstein, Lower Saxony, and North Rhine Westphalia. The German doctors in control of these provincial areas have powers which are partly official and partly derived from the professional organisation. It is a kind of compromise between a regional and a B.M.A. organisation. The cost of the organisation comes out of occupation costs, paid by the Germans, and supervised carefully by the High Commissioner's staff.

Some German members of the staff of the provincial organisations told me that there were large numbers of doctors in Germany unemployed. They would be willing to emigrate, but for service as doctors in such places as the British Dominions and Colonies they would need to speak, read, and write English, and not many of them can do this. It is also very doubtful whether the Dominions would take them in. Australia, which has been encouraging the immigration of Germans into her territory, is willing to accept German doctors as individuals—but not to accept them as doctors. Even this might attract some German doctors, for I heard of some of them being employed on farms in Germany. Lack of knowledge of English restricts the possibility of their employment by the Control Commission or the Armed Forces in Germany, though some of them work with the troops as civilian medical practitioners. Differences in their method of work and in their approach to patients also present difficulty. On the other hand there are men in Germany of high reputation in their specialties who could render valuable service as consultants.

Among the many people I met in Germany was a small group of German doctors, some of whom had

recently been to England to study our methods of training and employment of sanitary inspectors. I was told that if you ask a German whether his town employs sanitary inspectors he will say Yes. But he means only a man who clears the drains. The work of the British sanitary inspectors as a part of the health service was a revelation to the German doctors, for they did not know how much valuable work can be done by the kind of friendly and ubiquitous official we have in this country.

RECONSTRUCTION AND THE OCCUPATION

At the end of the war the displaced persons' problem in Germany was very large and very grave. Now it has shrunk to a much smaller size, and it is in theory to disappear next January when all D.P.s who remain in the camps (because they have refused to return to their countries or to emigrate) will automatically become German citizens. But there is still a stream of refugee-coming from Eastern Germany into the West, and these people present a problem not yet solved, especially as there is still much unemployment in the big towns of the Ruhr and elsewhere.

Signs of the bombing of Germany's towns and industrial establishments are to be seen everywhere. There are new buildings—some of very poor quality, erected very quickly—but it has not yet been possible to undertake anything like the rebuilding seen in London and other blitzed areas here. The destruction was, of course, far greater in Germany.

During this time of cold war, it is strange to find conditions so quiet and orderly in Berlin. One can drive through the city from the British to the American or the French or the Soviet sector as freely as in London—indeed much more freely, because there is very little motor traffic. The only difference is that anyone who goes into the Soviet sector must be ready to produce his identity card or passport at a moment's notice. Women employed by the Control Commission or Services and wives of Servicemen, habitually go into the Soviet zone to the theatre and ballet, which are excellent.

For the families of British personnel, life in Germany is pleasant, and Berlin is one of the most popular stations, because of sports and musical and theatrical attractions. In places other than Berlin, the British often have to live at long distances from their place of work. Some families are quite isolated and depend in emergency on German doctors and German hospitals. The general feeling towards them is reasonably friendly. In many parts of Germany there is little hostility towards Britain, and in Hanover the suggestion has actually been canvassed that the ancient link with England should be renewed by a member of the British Royal Family assuming the old Hanoverian throne.

One interesting development in Germany has arisen from the association now permitted between troops and civilian Germans. Some of the young soldiers have wished to become engaged and to marry Germans, and a number of marriages have taken place. In a large proportion these are said to have proved successful, and perhaps some of the credit should go to the method used by the Army and Air Force in dealing with applications for leave to marry. First an official request has to be made, and this in itself has an effect on the man who makes it. Secondly, if the man has not recently been on leave, he is sent on leave before a decision is made, and this sometimes causes him to change his mind. And thirdly he has the opportunity of discussing the question of marriage with an understanding and well informed superior. This cautious approach is salutary, and civilian society in England might well adopt a similar procedure.

* American troops stationed in Britain during the late war received their milk from the United States because no reliance was placed on the safety of British milk.—F.N.L.

surprised to see some blue blotches on the right dorsum. My surprise turned to mild dismay when I looked closer and found that the blotches looked like purpura. As far as I knew, 'X' could not have had this effect. It was also odd that there seemed to be no similar lesions elsewhere and my imagination now taking over I decided that the colleague who had administered 'X' might have put it by mistake into an artery.

Still dubious I walked over to the ancient monument whose steps we run up and down. I took off my jacket—and then put it on again and went back to the ward-round where I thrust my right hand at the professor, asking "Is this purpura?" "It certainly looks remarkably like it," he replied and then put on his spectacles and looked with some care. Finally he delivered judgment. This, he thought was not purpura although the lesions resembled it and it would be quite safe to run to exhaustion. I retired slightly discomfited and as I went, I heard one of the junior members of the unit make a remark which would have driven me to run myself silly even if the professor had thought it unwise. In a pedantic voice amid laughter from the rest of the unit, he declared "The lesions have the characteristics and distribution of senile purpura."

We peripatetics are careful to disguise our individuality, but we offer points of interest as a group and I have begun a preliminary classification. First there is the peripat—the bluff friendly, down-to-earth country GP whose practice consists of countermine with a fund of earthy knowledge of practical medicine. He speaks for a return to dock leaves and foxglove and he rather disapproves of the cold comfort of modern techniques. Then there is the peripateticist who is very different. He writes accurate but somewhat dry accounts of international meetings. There are also the peripateticians and peripatetologists, who are always experimenting with things like trombones and A.P.s. We must not forget the peripatetic correspondent who is bullied by his wife, his patients and the executive council, and who makes anonymous faces at Mr. Bevan from under the Editor's cloak. And for all I know Mr. Bevan himself yields a peripateticic quill. I strongly suspect that I sometimes see a peripatetitorial comment which is too ebullient to appear elsewhere in this journal.

The newcomer to general practice however well trained and conscientious must expect some snags if he starts his assistantship in a Derbyshire colliery town. For example at evening surgery a tough miner walks in and when I ask what his trouble is his answer sounds like "I want a lodjorge." "A what?" said I. "A lodjorge," he repeated, with an impatient frown. "double L O Y D G E O R G E." This still did not enlighten me so he got down to monosyllables. "I want to go on t club." But being a doctor of post-war vintage I was unenlightened so I consulted the head of the practice. After briefly reviewing the history of health insurance in Great Britain he explained that up North Lloyd George is looked on as the permanent head of all State insurance schemes, so they call all health certificates after him. The phrase, "To go on t club," is merely the jargon of friendly society days for "to go sick." Quite simple when one knew the answer. But when next day a man with a crushed toe asked to go on compo though this sounded to me like a kind of stewed fruit, I applied to my employer at once without first exposing my ignorance of the Workmen's Compensation Acts.

'Tea garden
Bear left
—So ran the notice. Eager and athirst
Thither we speedily inclined
Our faltering steps only to find
A sharry load had got there first.
Leaving behind
A bear garden
With no tea left.

As a reasonable gesture of good will to our statistician, Dr. R. has promised to stop referring to his "adjusted data" as "cooked figures."

Letters to the Editor

STUDY OF DELINQUENCY

SIR—The violence of the psychiatric onslaught upon me in your recent correspondence columns has set me wondering. Can it be that I have touched a tender spot? Dr. Paul Rewald the well known criminologist, has suggested that society needs the criminal as a focus for its guilt-feelings. Am I the felon upon whom psychiatric guilt feelings are being released? If so, the only psychiatrically respectable thing to do is to get at the cause of the guilt. And if I were allowed to indulge in a little diagnosis, I would suggest that this lies in the false position of the psychiatrist as such in the modern world. The short period of study hitherto required for his diploma is a quite inadequate training for the social responsibilities which he is called upon to undertake. Meanwhile our menacing "maladjustment" problem is virtually untouched, and will remain so until we have an adequate supply of social practitioners trained on realistic lines. The tradition furthermore, that the treatment of "mental illness" demands full medical qualification means that this supply is being artificially limited.

This social maladjustment of the psychiatrist is an historical commonplace. It is a re-enactment of the struggle of the medieval guild against the new class of artisan, of the hand loom weaver against the new manufacturing techniques and of the craftsman engineer against "dilution." It is in accordance with historical expectation then that many psychiatrists will fight to maintain their craft position and that those who advocate new techniques and a more realistic training will be the subject of their attacks.

Matters have been brought to a crisis recently not only by the deterioration in the nation's "emotional health," but also by the revolution in our knowledge during the last ten years (under the leadership be it admitted of the progressive wing of the psychiatrists, to which I have acknowledged my debt elsewhere). The object of my paper (Nov. 25) was to make some suggestions for the development of the new techniques rather than to demigrate psychiatrists as a class. And if I have created the wrong impression I hasten to correct it. Were I however to shirk a frank statement of the position for fear of treading on corns I should be failing in a social duty. It is a melancholy fact that we are at present allowing the personalities of many children to be so damaged that they are destined to become if not delinquent at least unhappy and unpleasant people who will create still more unhappiness both around them and in the next generation. Of the 90 delinquent youths of whom, in my recent study¹ I could obtain data about childhood, no less than 62 had shown gross symptoms of maladjustment or unadjustment before their tenth year. Nothing effective was done about them and indeed very few of them had had any contact with a clinic at all. Dr. Edelston's (Dec. 9) optimism about the spotting of the unhappy child is not justified.

There are many points in Dr. Bodman's letter (Dec. 2) which tempt me to reply but for reasons of space I must limit myself to his main taunt. Far from my generalisations being based on 'a few particular instances' or upon inexperience, as he suggests I have been in a unique position to assess the validity of a fairly representative cross section of psychiatric judgments. I have in fact been able to read a large number of psychiatrist's reports upon delinquent youths of whom I could subsequently make a detailed long term study. Not wishing to exacerbate interprofessional differences I only quoted

much difficulty in speaking to an audience. Rather, I was liable to find myself in ordinary conversation shouting some isolated and trivial phrase without intending it. Gradually I trained myself to keep pitch and volume level, and was then criticised for having a monotonous voice.

When my final examination was in sight I realised that if I wrote my papers as I had at school their brevity would condemn me to a third class. Permission was given for an amanuensis to type my papers. I had begun to type myself in my last years at school, but was not yet sufficiently proficient to manage examination papers. A first came as a surprise despite all my scheming to secure it. For the next two years I did research.

I came home with qualifications which would have sufficed to procure a job for a normal person. I had to discover a job in which my handicap would not hinder me, and then persuade someone to let me show I was capable of it. In the ensuing months both problems seemed insoluble. Obviously I had to tender a medical explanation of myself to any prospective employer: the term appearing on it was "cerebral diplegia," and I suspected that a prudent resolve to keep clear of the unknown (for the condition is still unknown to many people) would militate against my being employed. I am not sure whether in the aggregate other people's ignorance of the disability hindered or helped. In the end the problem solved itself. I was told by friends of a form of librarianship which they thought would suit me. I applied, was interviewed over—of all inauspicious things—a cup of tea, and was offered a job. At the end of a month I was told what I most wanted to hear—that I was doing the work of a normal person with no allowances made.

That perhaps should be the end of the story. In all these years, however, I had done little domestic work, because I was fully occupied elsewhere. Less than two years ago I changed my lodgings and began to cook and clean for myself. Friends, and even my mother, doubted whether I could manage it, but I knew domestic routine well enough and retained my old confidence that what I knew how to do I should eventually succeed in doing. As always, my ability increased with practice. In cooking, liquids are the only real difficulty, but I use large jugs and pans, from which I am less likely to spill. If I have occasion to fill a glass or cup I fill it where I am going to use it. When I had lived thus for several weeks I suddenly realised that I had come as near to self-dependence as do the majority of people in our complex civilisation.

Within the last two years also, I have benefited from specialised cerebral palsy treatment which was not to be had in this country until comparatively recently. One of its heartening results is that I am gradually finding myself able to write in something approaching the normal fashion. Looking back, I see myself acting as would any child experiencing a comparable disability offset by good general health and fair intelligence, but any success I have had in minimising my handicap I owe largely to circumstances. Foremost among these I would put wise handling in childhood, the chance of a normal education, and, finally, work in which to prove myself, with all that this means in confidence and serenity.

"Hospital experts tell us that for an efficient hospital service we require an increase in beds in the nature of 40% above the present accommodation. I suggest this is the wrong method of approach and that the main function of the hospital service should be to see in what way the number of beds could be reduced. This approach makes the problem much more difficult. It is far easier, if much more expensive, to treat existing patients than to carry out investigations into the cause of the illnesses and the means at our disposal of preventing them, with one exception: no Regional Hospital Board in this country has amongst its members a professional epidemiologist."—Dr HUGH PAUL, M.O.H. for

In England Now

A Running Commentary by Peripatetic Correspondents

ON Friday mornings the great amphitheatre is crowded to suffocation, one had never imagined that there were so many people in Paris interested in dermatology. The back four rows are full of students and nurses, a hundred or two. The middle benches are occupied by post-graduate students from all over metropolitan France, the colonies, and even the lands of dermatological heresy. Flemish mingles with the honeyed tones of Louisiana, heavily accented Breton with the gallicked staccato of southern lands. The front rows are reserved for senior colleagues and distinguished visitors, each of whom as he enters precipitates a fresh epidemic of hand shaking.

At last the Professor appears, *deus ex machina*. All stand until he waves them to their seats with a gesture both cordial and impatient. The cases rapidly succeed one another and are demonstrated to the throng with humour, skill, and touching humility. The audience is by no means passive and at times the scene recalls a cattle market, the poor beasts being prodded and pushed, the cries of claim and denial growing louder and more insistent until the hubbub is stilled by the thin high voice of the Professor rising above the din. What can the new student gain from such heated discussions of minutiae, from the distant parade of rarities, the moutons à six pattes? But the Professor is aware of his gallery, now there must be no dermatology through a telescope. This case must circulate, mark it well. It is a chance, whose owner looks more sheepish than the alleged owner of six legs.

The narrow road to consultant status is so hedged about by family commitments that when the principal of a practice in which I was once a part-time assistant telephoned to say his partner had a feverish cold I gladly accepted his invitation to help with an evening surgery. The waiting room was fuller than I had ever seen it in the old days, when a man of some 30 years presented himself. "I am quite well," he announced, "but I can't get up in the morning." My immediate reaction was sympathetic. There were no other symptoms, so here was a problem should a member of the College and a doctor of medicine allow a patient to come and go unexamined? This could not be, but neurological examination revealed no grave mischief. "What would you like me to do?" I inquired. "Can't you give me a bottle of something?" he said. The problem became more difficult. He was obviously the sort of man who would resent any treatment which prevented him enjoying a full night's sleep, and I had no wish to make him join the numerous gathering outside who required sleeping tablets. I suggested an alarm clock. "No use," he said, "doesn't touch me." "Can't your wife give you a nudge with her knee?" I asked. It seemed that she would be the next patient in and was suffering from sciatica. I presumed she had only one leg and bilateral disability of the arms, and pursued this line no further. "Mist Acid Strych," I wrote on the pad. "Thank you," he beamed. He rose to go and then remembered. "Can I have a certificate, please, and will you date it for last Monday? I've missed three days through this already!"

Have you ever had hysterical purpura? I have. It happens that I am carrying out some experiments on volunteers, and, as seems only fair, I myself act as one of the principal guinea-pigs. On the day that I developed my hysterical manifestation, I had an injection of "X" and then ran up and down a long flight of stairs until exhausted. I managed more than 1100 stairs up and down and decided this was not a bad performance being close on 40 and not a great one for exertion. Unfortunately, the programme called for a similar burst two hours later. I excused myself from the professorial ward round and went down to the laboratory torn between a desire to know the results of the experiment and a strong distaste for taking too much exercise twice in one day. Happening to glance at my hands, I was

it was necessary to open both pleural cavities and excise a segment of the pericardium and 2 in. of the left innominate vein.

The tumour was very vascular, and the advantages of the continued use of diathermy precluded the addition of cyclopropane or ether which would have been indicated in view of the unusual resistance of this patient to thiopentone. A trial dose of decamethonium iodide 0.5 mg. was then given, and as no effect was discernible after 5 minutes a further 2.5 mg. was injected. This caused no obvious respiratory paralysis but "assisted respiration" was facilitated. A total dose of 7.5 mg. of decamethonium iodide was used over a period of 35 minutes. There was a 5 minute period of intercostal paralysis at no time was it possible to control respiration completely, but adequate ventilation and a steady mediastinum were obtained.

Recovery from both the decamethonium iodide and the anaesthetic was rapid and uneventful. Atropine gr. $\frac{1}{50}$ and neostigmine 2.5 mg. were given intravenously, at the conclusion of the operation an intramuscular injection of atropine gr. $\frac{1}{100}$ and neostigmine 5 mg. was given half an hour later, by which time the patient had regained consciousness. The subsequent postoperative course has been uneventful.

I am of the opinion that the tolerance of this myasthenic patient was certainly no less, and was possibly slightly greater, than would have been expected in a normal patient of similar build.

My thanks are due to Dr Douglas McAlpine and Mr T. Holmes Sellors.

A SIMPLE LOW-SODIUM RÉGIME

SIR,—Although the cause of oedema in congestive heart failure is still obscure, the value of sodium restriction in the management of this condition is firmly established.^{1,2} While severe water restriction has been abandoned, most workers are averse to forcing fluids as Schemm⁴ advocates, but give only as much water as the patient desires.^{2,3}

There is less unanimity on the optimal degree of sodium restriction, and this is reflected in the variability of salt content (from 1 to 3 g.) in the routine low sodium diets of different teaching hospitals.^{5,6} In the treatment of hypertension, maximal levels have been fixed variously at 500 mg.,⁷ 250 mg.,⁸ and 150 mg.⁹ per day. But in the treatment of congestive heart failure, where salt excretion must be forced by mercurial diuretics, extreme restriction of dietary sodium increases the risk of precipitating uremia, especially in the elderly,¹⁰ in whom cardiac and renal impairment often coexist. Probably the optimal intake in the management of congestive heart failure lies between 250 and 750 mg. of sodium per day.

Even under strict supervision in "metabolic units" the actual dietary sodium may be 50% greater than the calculated amount,⁵ while the "low salt diets" of the less well supervised kitchens of many hospitals are a myth. On the "salt-free" diets of two large hospitals employing dietitians and kitchen supervisors, normal individuals excrete up to 8 g. of urinary chloride per day.¹⁰ Routine use of the Fantus¹¹ test for urinary chloride (and hence a rough but useful estimate of urinary sodium) demonstrates the difference between prescription and treatment.

In a hospital admitting large numbers of elderly patients in acute and chronic congestive heart failure, the "salt free" diet had been proved unreliable and attempts to improve it abortive. As a low sodium régime of known and fixed constitution was necessary both for treatment and for research, Karell's¹² simple "cure de lait" was modified, with the foregoing desiderata in mind, and has proved eminently satisfactory as short term therapy. The original "milk cure" provided too small a fluid intake and too low a calorie value to be acceptable.

4 pints (2250 ml.) daily of a mixture of equal parts of milk and water are given by mouth, the patient being allowed in addition as much water as he wishes. This diet contains approximately 570 mg. of sodium and is equivalent to about 750 calories.¹³ (The sodium content of Oxford's tap-water is 7-10 mg. per litre.¹⁴) It has commonly been fortified with extra protein by the addition of calcium caseinate up to 3 oz. (90 g.) per day (as 'Casilan,' Glaxo), which increases its calorie value to about 1050 and its sodium content to 650 mg. The régime is continued for no longer than 14 days.

On this diet normal individuals "stabilise" their urinary chloride excretion at 2-3 g. per day within 2-5 days. In over 150 cases of congestive heart failure with oedema, it has provided a simple and satisfactory means of ensuring dietary control in the early stages of treatment.

The only claims advanced for this modified Karell régime are (1) it is simple to prepare and can readily be managed by a ward sister or a busy housewife, (2) its constitution is known, and its sodium content is as low as the low sodium régimes of well-equipped and well supervised hospitals, and (3) it provides an adequate fluid intake.

Its disadvantages are (1) as with all low sodium régimes, monotony and unpalatability, though no difficulty has been experienced in achieving willing perseverance for a fortnight, (2) low calorie value, but this has proved no handicap over so short a period, (3) too high a sodium content for the proper treatment of hypertension.

This régime is not meant to supersede formal low sodium diets where supervision is adequate. But where adequate supervision cannot be exercised, as in general practice and in many hospitals, this simple low sodium régime may ensure dietary control during the initial stages of treatment of congestive heart failure.

P. D. BEDFORD

VITAMIN K IN ALLERGIC PURPURA

SIR,—In your leading article of Dec. 2 you refer to the lack of a reliable specific remedy in Henoch Schönlein purpura and other conditions.

I have treated 3 cases of allergic purpura, showing manifestations of the Henoch Schönlein syndrome, with synthetic vitamin K, with resulting rapid recovery.

In the 1st of these cases a large spontaneous ecchymosis (5 in. by 3 in.) occurred on one shoulder with several smaller ecchymoses on the thigh of the same side. Shoulder and knee joints on this side were swollen red and tender. All blood tests were normal, except the prothrombin time (Quick), which was 60 sec. (normal control 16 sec.) After one week's treatment with synthetic vitamin K (20 mg. orally t.d.s.) the condition had resolved and the prothrombin time was 13 sec. (control 13 sec.)

In the 2nd case there was a long family history of allergy. The patient, a woman from time to time had small ecchymoses on her limbs. There were no joint alimentary or renal signs. Prothrombin time was 26 sec. (control 16 sec.) All other blood findings were normal. The condition again cleared up rapidly with vitamin K, and one week later the prothrombin time was 15 sec. (control 14 sec.)

one or two which I needed for the demonstration of prevalent diagnostic errors. Were I ever provoked into the publication of the remainder, it would be seen that the general run of the "psychiatric examinations" were very haphazard affairs. The reports of different psychiatrists upon the same boy were sometimes flatly contradictory, and the general lack of psychological knowledge and disciplined scientific thinking were maladroftly disguised by long words and nearly meaningless shibboleths.

But I must drag myself from the pleasures of polemic to make some positive suggestions. Mental ill health, it is now realised, has its roots in childhood, which means in our family life or wherever children are. The main damage is done before the patient comes to the clinic. The spotting of the unhappy child in his pre delinquent, pre neurotic, or pre psychotic period must be the work of those who have continuous contact with the nation's children. This means that the elements of emotional hygiene must form part of the training of the school teacher, club leader, school welfare officer, and probation officer, and above all of the family doctor.

Furthermore I am certain that the essentials of the modern personality psychology, with its straightforward analysis in terms of human relationships and basic emotional needs, is simple enough to be handled by these varied types of social practitioner. If, for example, we acted on the principle that every human being, to remain emotionally healthy, must feel secure as a member of a small "belonging group," we would largely solve our "maladjustment" problem. Yet one hears of cases where shock therapy and other more drastic measures are resorted to without any attempt to readjust the patient's human situation. It is for this reason that I have emphasised the need for guides to observation which will direct the attention of the non specialist social practitioner to the patient's defective human relationships, and indicate to him the most likely causes of the anxiety and the seriousness of the false adjustment.

One might say that, with their main work lying in other directions, the doctor, school teacher and social worker should be equipped to render psychological first aid. The case needing more than advice upon common sense lines would be handed over to the fully trained worker in mental health.

Even the psychological specialist does not require to work through the full medical course. And the three years which would be the minimum for his becoming a competent psychologist, after the 4-5 years of his general course, would surely discourage the student at a time when many more clinicians are required. The general medical course would probably burden him with much he would never need, and not go far enough along other lines. After a discussion with a lecturer in anatomy at a London training hospital, during which I raised a number of neurological points which interested me as a psychologist, he surprised me by saying "I never touch upon any of these things in my lectures." The psychologist, then, would apparently require much more neurology than the general practitioner and less general anatomy and pharmacy.

The issue is more than a personal one between academically and medically trained psychologists. In my report I suggested that the poor results achieved by psychology as a science were in part due to the one sidedness of the training of each. It is rather a question, then, of re thinking and re planning the professional training both of the general social practitioner of every kind and of the mental specialist in the light of our present social needs.

HERPES ZOSTER AND VARICELLA COMPLICATED BY PARALYSIS OF THE TRANSVERSE COLON

SIR,—The following case has some interesting features.

On Nov 9, 1949, the patient, a man aged 79, was suddenly attacked by pain in the hepatic region. The next day herpes zoster manifested itself, and spread rapidly over the skin area supplied by the 8th, 9th, and 10th dorsal nerves of the right side. Pain was intense, especially over the epigastrium.

On Nov 13 widespread but discrete varicella vesicles appeared on trunk and extremities, with a few scattered vesicles on the scalp. The herpes vesicles had become confluent, and the affected area was covered with large bullae. Pain was still severe. On Nov 18 'Aureomycin' 250 mg once daily was started, but this was discontinued after a week because no benefit had been noted. By Nov 20, the herpetic bullae had all broken and the area had the appearance of a third degree burn.

On Dec 12 a disturbing sensation of coldness and weight suddenly developed in the situation of the transverse colon. From this time forward no natural motion of the bowel occurred until Jan 20, 1950. A number of laxatives and purgatives were taken, but these caused only distension and distress. It appeared that peristalsis in the transverse colon had ceased and relief was not obtained until high colon washouts were commenced. During these, discomfort in the region of the hepatic flexure was pronounced, and a quantity of scybala came away towards the termination of the return of the enemas. On Jan 16 a barium enema was given and subsequent X ray examination revealed nothing abnormal. During the thirty nine days that this condition persisted the patient's condition deteriorated, he lost 28 lb in weight and vomited several times, depression was intense.

On Jan 19, against medical advice, the patient took a heroic dose of magnesium sulphate (1½ oz), bringing away quantities of scybala. From this time onwards bowel action was normal. However, post-herpetic pain continued over the site of the zoster area, and there has been a persistent dragging and tearing sensation in the abdomen, especially over the transverse colon. On April 17, weekly application of radiotherapy to the zoster area were commenced, but these were discontinued after the third application because no improvement had taken place. At both sites pain persists twelve months after the onset.

It appears that in this case herpes zoster has involved not only spinal nerves but the sympathetic innervation of the transverse colon.

SURGEON

DECAMETHONIUM IODIDE IN MYASTHENIA GRAVIS

SIR,—In their article of Nov 18 Dr Paton and Dr Zannis discuss the difference in mode of action of *d* tubocurarine chloride and decamethonium iodide in producing neuromuscular block. They refer to the well known idiosyncrasy to tubocurarine in myasthenia gravis and suggest that no such idiosyncrasy is to be expected in the case of decamethonium iodide.

The following description of the use of decamethonium iodide during the course of thymectomy for myasthenia gravis confirms this view.

Early this year a tall, heavily built policeman developed diplopia, ptosis and increasing muscular weakness. Neostigmine up to 30 mg two hourly with atropine gr 1/100 had been required to stabilise him but his disability was increasing and it was decided to perform thymectomy.

He received his usual dose of neostigmine and atropine three hours before operation, and 'Omnopon' gr 1/2 and scopalamine gr 1/100 were given one hour before. 0.75 ml of 10% cocaine solution was injected through the cricothyroid membrane to anaesthetise the larynx and trachea. Induction by thiopentone 1 g was followed immediately by oral intubation, using a cuffed tube. 2 litres per minute each of nitrous oxide and oxygen were administered by means of a semi closed circuit with circle adsorber and repeated small doses of thiopentone were injected into a saline drip.

A sternum splitting approach to the anterior mediastinum was performed by Mr T Holmes Sellers and a malignant tumour of the thymus was discovered. During its removal

STRIÆ CUTIS DISTENSÆ

SIR,—The following case is reported because of the recent interest^{1,2} in coloured lineæ distensæ developing during an infection—

A tall, thin weedy boy, aged 17, was admitted on Aug. 6, 1949, having been ill for a week. He was found to have a large right-sided pleural effusion. Diagnostic thoracentesis on Aug. 8 below the angle of the right scapula in the 8th intercostal space produced clear straw coloured lymphocytio fluid. No organisms were seen, culture and guinea-pig inoculation showed no evidence of tuberculosis. On Aug. 15 I examined him again and was surprised to find extensive purple lineæ distensæ on his back—they had certainly not been there 7 days earlier. They were more numerous on the side of the effusion and over the lower lumbar area they were wider and longer. Pyrexia gradually settled during the next 3 weeks and the patient was discharged well after 4½ months rest, having gained 17 lb (8 st 10 lb on admission, 9 st 13 lb on discharge). He was seen again in January and September, 1950 and has remained well. Chest radiography shows residual pleural thickening only. There was no evidence of an endermopathy. Urinary excretion of 17 ketosteroids was 5.6 mg per day on Sept. 30, 1950 (normal male 8–22 mg per day). The clinical course was that of a primary tuberculous effusion.

The lineæ distensæ were still purple though less so when seen in September—they were wider, longer, continuous in some places across the midline, and more marked on the left side. Over the sacrum they had faded from purple to white.

The appearance of red or purple lineæ distensæ has been noted during treatment with 'Cortisone,'^{3,4} and Simpson⁵ has stated that where they are found clinically "one can conclude with reasonable confidence that there is hypersecretion of adrenal cortex hormones." Medvei¹ adduced a case in a youth with lobar pneumonia as an argument against the view of Simpson⁵ that coloured lineæ distensæ are due to "the adrenal glands secreting an excess of cortisone, and that their hyperfunction is, therefore, playing an important part in the pathology of the condition observed." Selye,⁶ however, states that the "general adaptation syndrome" may develop as the result of "non specific stress"—an infection may produce the hormonal defensive response, which is accompanied by an increase in the secretion of ACTH—a "glucocorticotropic" hormone which induces the adrenal cortex to produce cortisone. I suggest that in the case reported above the stress of infection induced the increased production of cortisone, which was manifested in the coloured lineæ striæ.

Persistence of the purple colour should mean continued high production of cortisone, the result of continued stress, and this is a reasonable hypothesis in a case of primary tuberculous effusion, which carries a 20% risk of pulmonary tuberculosis, usually developing within five years. In addition to this possible source of stress, my patient shows signs of possible genetic inferiority. He is surly, unappreciative, and a poor mixer. During 4½ months in hospital he never "adapted" himself to his circumstances, refused to occupy his time usefully, and never shared the cheerful atmosphere of the convalescent home. In this case, then, continued stress could be explained by a primary tuberculous effusion, poor physique, with rapid skeletal growth, and unusual personality. From the clinical facts that Medvei gives it is impossible to speculate why his "tall, slim, well built youth," aged 20, with lobar pneumonia should have had persistent purple striæ after 6 years, but it is tempting to wonder whether the diagnosis was unequivocal, since the possibility of a primary tuberculous pleurisy would simplify the explanation.^{2,4}

The distribution of the striæ in the present case calls for comment.

They were predominant on the right side, that of the effusion. The right side of the chest moved little on respiration, and, though the effusion was large and must have increased the volume of the chest on that side, clinically and radiologically there was no evidence either that the ribs were more horizontal than normally or that the intercostal spaces were enlarged and obliterated. Distension is usually accepted as the explanation for the site of coloured striæ in pregnancy, Cushing's syndrome, and during treatment with cortisone. This conception that distension causes a cleavage in the deeper parts of the cutis possibly due to deficiency of elasticity, is rather naïve, it is surely more acceptable that distension merely determines the site of lesions to which there is already a predisposition. In the present case there was no gain in weight coincident with the appearance of the striæ, and even if there had been there is no satisfactory explanation of why the striæ appeared on the back especially as "pressure areas" were not affected. Perhaps the predominance of lineæ on the right side was determined by either the underlying disease, by distension of the right hemithorax that was not recognised clinically, or (which is unlikely) by greater pressure on the skin on that side because, to breathe more easily, the patient would tend to lie with the sound lung uppermost. No association was noted between the site of needle puncture for the thoracentesis and the development of the striæ. The subsequent redistribution of striæ in position, length, and width, and the fading of some to white while new purple ones appeared is equally mysterious.

Parkes Weber⁷ has shown special interest in striæ occurring "in the absence of the ordinary causes" and has suggested⁸ that "the relative insufficiency of the cutis, which is a part factor in the causation of the cutaneous striæ in so-called 'idiopathic' and post infection cases, may be due to a temporary basophilic hyperpituitarism associated with the period of rapid growth at and following puberty." The striæ seen in cortisone treatment, and my suggestion, are therefore anticipated by 18 years.

The increased output of cortisone in pregnancy is satisfying confirmation of the old observation that rheumatoid arthritis and peptic ulcers improve spontaneously during pregnancy. If coloured lineæ striæ can be accepted as evidence of an increased production of cortisone, this simple clinical observation opens up many possibilities. How often do pregnant women with rheumatoid arthritis get purple lineæ? It is my impression that abdomens showing purple lineæ during pregnancy, and those young parous women with much striated abdominal skin, as flabby as a balloon half filled with water, belong to a group where "stress" may be active. Perhaps it could be shown that purple striæ—their position on the abdomen favoured by distension—are associated with increased production of cortisone due to a combination of pregnancy and stress. It would be interesting to know whether they ever appear so suddenly as to be fully developed in seven days, and, if this happens, whether there is then an association with stress and not with distension.

Perhaps adolescents develop purple striæ with special ease, five of the six patients of Sprague et al.⁴ on cortisone were aged 17 or less. My impression is that the younger the woman the more extensive are the purple striæ. Most people will be acquainted with the ragging that the lanky adolescent three quarter comes in for in the rugger changing room because someone spots the purple lineæ "gravidarum" on the upper outer part of his thighs. School and Service medical officers have a good opportunity of confirming this observation and noting in such cases any additional stress beyond that of adolescence. Perhaps something of interest might come of watching for persons with purple lineæ from

In the 3rd case symptoms developed after three daily injections of crystalline penicillin G, administered for cellulitis of the leg. There was massive purpura, involving both lower limbs and the lower abdomen, with joint swelling of both knees, ankles, wrists, and fingers. There was an effusion into the knee joint on the side with the original cellulitis. Various anti-histamine preparations were administered, with no effect. Oral and intramuscular vitamin K was then administered, with rapid improvement and eventual resolution. Unfortunately, in this case it was not possible to perform blood investigations. However, allergic purpura has been reported as a complication of penicillin therapy,¹ and there seems little doubt that it was so caused in this case.

Vitamin K may not be a specific remedy for Henoch-Schönlein purpura. Nevertheless, when deficient in the body it is a clot-promoting agent, and it might well be tried in these conditions.

DAVID WHEATLEY

OCCUPATION AND BRONCHIAL CARCINOMA

SIR,—The present acute interest in the aetiology of carcinoma of the lung is reflected in Professor Dungal's article (Aug 12), your leading article in the same issue, and the letter from Sir Ernest Kennaway (Sept 23) which drew attention to the increasing incidence of this disease. More recently Doll and Bradford Hill² have published evidence implicating smoking as a causal factor.

The relation of occupation to this disease has long been a subject for speculation. Some years ago I collected data on occupation in 172 cases of certified deaths of males from carcinoma of the lung in the Metropolitan borough of Islington.

A difficulty in relating occupation to disease is that nothing may be known about the duration of the occupation, and further, in old patients the occupation may have ceased many years previously (although this need not rule out the occupation as a causal factor). Moreover, an apparently increased incidence in any one occupational group may only indicate an aggregation of persons employed in this occupation in the area under

review. These 172 cases covered no fewer than 88 separate occupations, and it was essential to condense these into a smaller number of occupationally related classes. When this was done it was found that the classes did not correspond with the occupational grouping for males shown in the official census returns for Islington. In order to overcome this difficulty, and to attempt a standard of comparison, I compared the occupational incidence of carcinoma of the lung with the incidence of deaths from cancer of all other sites in the same occupational groups. When in an occupational group, the ratio of deaths from carcinoma of the lung was high in proportion to deaths from cancer of all other sites, this would suggest that occupation was a possible causal factor. In the accompanying table columns 1 and 2 show the deaths of males from cancer of all other sites in each of the years 1932 and 1936, and column 3 shows the total of deaths from bronchial carcinoma in the 5 years from 1932 to 1936.

The numbers in each group are too small to be of statistical significance, but the four groups in which the proportion of lung cancers is highest are (1) railway workers, engineers, smiths, iron foundries, (2) GPO workers (including postmen), electricians (5 of the 10 lung cancers in this group occurred in electricians), (3) motor drivers, car-washers (6 of the 13 cancers in this group were in taxi drivers), (4) waiters, café workers, bakers (5 of the 10 were bakers). In groups 1, 3, and 4 inhalation of combustion products from coal, coke, or petrol might occur, but it is difficult to put group 2 (electricians, &c.) in this category.

This limited investigation proves nothing, but it may be of value to future investigators.

Colindale Hospital London NW 9

W E SNELL

PREPARING FOR GENERAL PRACTICE

SIR,—The views on general practice in this country expressed by three visiting deans of American medical schools, on which you commented in your issue of Oct 28, are in general agreement with the Collings Report,¹ and are, in my view also, only too correct.

Whatever the general practitioner may have been in the past, to describe him today as the backbone of the profession is nonsense. In my 28 years of general practice there has been a vast increase in the number and variety of specialists, and this growth of specialisation has been accompanied by a corresponding decline in the clinical importance of the general practitioner. Today he is often little more than a mere signpost and disher out of placebos.

The most important factor in the debasement of general practice is, to my mind, competition between general practitioners for goodwill. The patient can and often (I might almost say usually) does bring economic pressure to bear on his general practitioner, in order to secure the type of medical treatment he wants. This enforced pandering to the whims and, often, ignorance of patients tends in the long run to induce clinical demoralisation of even the most strong-minded and conscientious of general practitioners. I do not deny that competition can be useful in stimulating laggards to greater attention and even civility to their patients, but this advantage is, in my view, heavily outweighed by the damage done, not only to the practice of good medicine, but in turning those who would otherwise be friendly colleagues into distrustful, isolated competitors. It also results in enormous waste of public money on useless medicines.

Let us be paid either by salary or, like consultants, by session, but at all costs let us be done with competition for patients.

of elastic fibres, with disappearance of these elements in places, and clumping and fragmentation of the elastic in other areas. There was no evident pigmentation and no obvious local change in the blood vessels.

Though only single estimations of ketosteroid excretion were possible, the change in the 20 ketosteroid values while the 17 ketosteroid excretion remained practically stationary appears highly significant.

Increased production of glucocorticoids is thought to mobilise glucose from the body proteins. The skin is the largest organ of the body, and represents about 16% of the total weight of an adult. It therefore seems reasonable to suppose that the skin supplies much of the protein used for gluconeogenesis, is weakened thereby, and becomes more liable to injury. Increased tension on skin so affected, due either to posture as described by Hurford and Snell,¹ or to the accommodation of deposits of subcutaneous fat or a space occupying lesion, such as an intra abdominal tumour, may well produce the histological features of strain cutis distensæ.

The normal glucose tolerance curve seems to confirm Simpson's suggestion⁴ that increased adrenal cortical output is balanced by a secondary hyperinsulinism. This may be a factor in determining the gain in weight.

I am indebted to Mrs A. M. Robinson for the ketosteroid estimations and to Dr R. J. R. Cureton for histological examination of the skin. I am also grateful to Dr H. C. Aston, of Bethnal Green Hospital, for permission to publish the case, and to Dr E. F. Scowen for criticism and advice.

D'ALMEIDA KOK

GERMAN MEASLES IN GIRLS' SCHOOLS

SIR,—Recently my youngest child, a girl of 6½, developed rubella. The attack upset the child mildly for a day or two, and at the end of 10 days she returned to school. (I understand that the latest Ministry circular recommends 7 days' exclusion from school from the appearance of the rash.) Apparently her return was too early to be in accordance with the "regulations" and she was told to keep away from the other girls.

I feel that enough is already known about the effects of rubella on the foetus in early pregnancy to warrant revision of such "regulations" as these. For my part, I am thankful that in years to come my daughter is unlikely to present me with a maimed grandchild, consequent upon an attack of rubella in early pregnancy. It seems a pity that the "regulations" prevent her from conferring this great boon on her school friends. It may well be that in time to come deliberate infection of girls with rubella during their school days will be offered along with vaccination, diphtheria immunisation and the rest.

TERENCE G. ROBINSON

UMBILICAL-CORD BLOOD

SIR,—Dr Lehmann's letter earlier this year,⁵ on the disturbance of prothrombin time estimations by cleaning the glassware with soapless detergents, demonstrated the value of communications on purely technical matters in your correspondence columns. It is with this letter in mind that I record a finding that may be of assistance to workers in the field of rhesus blood groups.

Occasionally samples of umbilical cord blood are contaminated with an undue amount of Wharton's jelly. While this is usually removed by simple washing as in the Coombs test, rarely the clumping of the test cells in suspension due to this viscous connective tissue mucus is not overcome by washing, occasionally also a rapid slide test is called for. When the phenomenon

has been encountered in this laboratory we have found that the addition of a small amount of a commercial preparation of hyaluronidase (one drop of a solution containing 1 mg. in 10 ml. of saline to tube or slide) will prevent the clumping, which interferes with the interpretation of tests. It has been found, further, that much higher concentrations of hyaluronidase do not interfere with any routine blood grouping procedures.

W. S. KILLPACK

PYREXIAL TREATMENT OF ULCERATIVE COLITIS

SIR,—In the early days of treatment of general paralysis of the insane by artificial pyrexia, a male general paretic was admitted to one of my wards at the County Mental Hospital, Ramhill. In view of his very poor general condition, complicated by long standing ulcerative colitis it was at first thought inadvisable to attempt pyrexial therapy, but at the insistent request of his wife a modified course of 'Pyriser' was given. It was observed with surprise that after the fourth intravenous injection the diarrhoea ceased. From that time onwards the stools showed satisfactory formation and there was no further evidence of colitis. Unfortunately the patient died a few months later as a result of his cerebral disease, and no conclusions could be drawn from the short period of apparent cure of the ulcerative colitis.

It was then brought to my notice that a male patient in another section of the hospital was suffering from ulcerative colitis of nearly two years' duration, and it was decided to study the effects of pyriser. The following notes have been extracted from his case sheet.

1931—May 19 taken ill with diarrhoea. Stools containing blood and mucus afebrile. May 26 Flexner organisms isolated from stools. Case notified to medical officer of health as bacillary dysentery. June 12 passing blood and mucus in stools. General condition failing. June 14 stools still show blood and mucus, no organisms of dysentery group now isolated, febrile, 99–103°F, general condition poor. June 28 Bowel condition as before, commonly febrile in evening, slight improvement in general condition.

1935—April 26 diagnosed as chronic colitis, average of six motions daily, often containing blood and mucus.

1936—March condition unchanged. April 4 to May 11 course of twelve injections of pyriser producing on all occasions (except the third injection) temperatures of 103–104°F. No blood or mucus found in the stools after the third intravenous injection.

1937—Feb 17 no further diarrhoea. No change in mental state.

1941—Nov 12 reported diarrhoea. Nov 14 Solimutz organisms isolated, 'Chinosol' exhibited for one month (details not given).

1942—Jan 15 clinically and bacteriologically clear, no evidence of colitis.

1947—March 28 attack of vomiting, occult blood in stools, presumably acute gastritis (no evidence of active colitis).

1948—April 13 reported to have loose stools. April 14 stools contained Sonne dysentery organisms but no blood or mucus, treated with phthalylsulphathiazole emulsion. May 25 six swabs have been negative (no evidence of active colitis).

1950—May 31 no clinical signs of colitis.

In the ten years after leaving Ramhill Hospital in 1938 I was able to use this therapy in a few cases in another hospital. The results were reasonably good, but they were complicated by the fact that the pyriser available during the war years produced less fever. The ampoules had all been filled before September, 1939, and their potency, in my opinion, decreased with time. Using the fresh supplies obtained in recent years the previous pyrexial response has been observed.

I can draw no definite conclusions from the small number of cases of chronic ulcerative colitis which I have been able to treat in the course of mental-hospital

whatever cause and using them as donors to transfuse a series of patients with rheumatoid arthritis.

Finally it may be that "idiopathic" purple lineæ distensæ are a manifestation of primary tuberculous infection, and further observation may put their appearance on a level with phlyctenular conjunctivitis and erythema nodosum as a warning sign.

I am indebted to Dr J O Perry for permission to publish this case.

Worcester Royal Infirmary

C ROMER
Medical Registrar

SIR,—Hurford and Snell¹ reported the development of purple striæ in 32 patients with pulmonary tuberculosis. They reviewed the literature on the subject and discussed the factors thought to be of aetiological importance. They concluded that the striæ result from several concomitant circumstances: (1) long continued local stretching of the skin (related in their cases to the posture adopted during treatment), (2) endocrine activity at puberty, and (3) an inborn constitutional tendency to develop striæ in the presence of the preceding factors. They did not think that the site of the disease in their cases had any definite relation to the site of the skin lesions. An increase of weight occurred in less than half of their patients, and they thought that neither this nor toxæmia was important aetiological.

Sprague et al.² record the development of reddish purple striæ during 'Cortisone' therapy. The colour remained for several weeks after the drug had been stopped. Simpson³ states that "where red and purple lineæ distensæ are found clinically, one can conclude with reasonable confidence that there is hypersecretion of adrenal cortical hormone." The following case is therefore of interest.

A male tailor's presser, aged 18, thought he had "been losing some weight recently." He had developed malaise a fortnight before going to see his doctor, and was then admitted to hospital with a temperature of 101.6°F, and a large right-sided pleural effusion of clear straw coloured fluid, from which tubercle bacilli were subsequently cultured. No other abnormal physical signs were found. The patient was of medium height and asthenic build, and was reasonably well covered.

Fig 1—Striæ cutis distensæ

Fig 2—Progress chart

Treatment consisted in rest in bed as much food as he could take, and extra vitamins, including 100 mg of ascorbic acid t.d.s. by mouth.

Progress—His appetite was poor for the ensuing three weeks, during which he seemed to become thinner. Thereafter he began to eat well, and he felt well during the rest of his stay in hospital. Five weeks after admission, during a routine examination, transverse purple striæ were noticed on his back in the lower dorsal region. At this time he had put on only 4 lb in weight (from 8 st 8 lb to 8 st 12 lb). There was still slight fever. The erythrocyte sedimentation rate (E.S.R.) had fallen to 18 mm in first hour (Westergren). As the effusion showed no sign of absorption, a pint was aspirated eight weeks after admission. The lineæ had increased in extent, to involve the lumbodorsal, and to a slight extent the sacral, regions (fig 1). Firm pressure with a glass slide produced incomplete blanching. A tourniquet test was therefore done (100 mm mercury for five minutes), which showed slightly increased capillary fragility. Ten weeks after admission the patient's temperature had fallen below 98.4°F, the E.S.R. was 14 mm in first hour, and he weighed 9 st 6 lb (fig 2).

Investigations—A blood count showed 5,080,000 red cells per c mm, Hb 96%, white cells 11,600 per c mm (polymorphs 55%, lymphocytes 32%, monocytes 10%, eosinophils 2.5%, basophils 0.5%). An ascorbic acid saturation test (700 mg given by mouth) showed that 180 ml of urine in 2½ hours contained 92 mg of ascorbic acid. A glucose tolerance test gave the following results:

Fasting	65 mg per 100 ml	No glycosuria
30 min	110	
90	140	
120	120	

The blood protein level was 7.5 g per 100 ml (albumin 5.0 g, globulin 2.5 g). The serum sodium level was 343 mg per 100 ml, and serum potassium level 19.6 mg. The urinary excretion of 17 ketosteroids was 8.9 mg per day (normal in adult males 7–15), and 20 ketosteroids 0.5 mg (normal 1–3).

Further Progress—Thereafter though the pleural effusion persisted, the clinical improvement was maintained. After fifteen weeks in hospital the patient was transferred to a pleural effusion unit, at which time he felt very well and weighed 10 st (an increase of 20 lb). The E.S.R. was 6 mm in first hour. The striæ had increased slightly in number and were still purple. The urinary excretion of 17 ketosteroids was 8.5 mg per day and 20 ketosteroids 2.7 mg.

Biopsy of striæ showed in the centre of the specimen beneath a rather atrophic epithelium evidence of destruction

of elastic fibres with disappearance of these elements in places, and clumping and fragmentation of the elastic in other areas. There was no evident pigmentation and no obvious local change in the blood vessels.

Though only single estimations of ketosteroid excretion were possible, the change in the 20 ketosteroid values while the 17 ketosteroid excretion remained practically stationary appears highly significant.

Increased production of glucocorticoids is thought to mobilise glucose from the body proteins. The skin is the largest organ of the body, and represents about 16% of the total weight of an adult. It therefore seems reasonable to suppose that the skin supplies much of the protein used for gluconeogenesis, is weakened thereby, and becomes more liable to injury. Increased tension on skin so affected due either to posture, as described by Hurford and Snell,¹ or to the accommodation of deposits of subcutaneous fat or a space occupying lesion, such as an intra abdominal tumour, may well produce the histological features of *striate cutis distense*.

The normal glucose tolerance curve seems to confirm Simpson's suggestion² that increased adrenal cortical output is balanced by a secondary hyperinsulinism. This may be a factor in determining the gain in weight.

I am indebted to Mrs. A. M. Robinson for the ketosteroid estimations, and to Dr. R. J. R. Cureton for histological examination of the skin. I am also grateful to Dr. H. C. Aston, of Bethnal Green Hospital, for permission to publish the case, and to Dr. E. F. Scowen for criticism and advice.

D'ALMERO KOK

GERMAN MEASLES IN GIRLS' SCHOOLS

Sir,—Recently my youngest child, a girl of 6½, developed rubella. The attack upset the child mildly for a day or two, and at the end of 10 days she returned to school. (I understand that the latest Ministry circular recommends 7 days' exclusion from school from the appearance of the rash.) Apparently her return was too early to be in accordance with the "regulations," and she was told to keep away from the other girls.

I feel that enough is already known about the effects of rubella on the foetus in early pregnancy to warrant revision of such "regulations" as these. For my part, I am thankful that in years to come my daughter is unlikely to present me with a maimed grandchild, consequent upon an attack of rubella in early pregnancy. It seems a pity that the "regulations" prevent her from conferring this great boon on her school friends. It may well be that in time to come deliberate infection of girls with rubella during their school days will be offered along with vaccination, diphtheria immunisation, and the rest.

TERENCE G. ROBINSON

UMBILICAL-CORD BLOOD

Sir,—Dr. Lehmann's letter earlier this year,³ on the disturbance of prothrombin time estimations by cleaning the glassware with soapless detergents, demonstrated the value of communications on purely technical matters in your correspondence columns. It is with this letter in mind that I record a finding that may be of assistance to workers in the field of rhesus blood groups.

Occasionally samples of umbilical cord blood are contaminated with an undue amount of Wharton's jelly. While this is usually removed by simple washing, as in the Coombs test, rarely the clumping of the test cells in suspension due to this viscous connective tissue mucus is not overcome by washing, occasionally also a rapid slide test is called for. When the phenomenon

has been encountered in this laboratory we have found that the addition of a small amount of a commercial preparation of hyaluronidase (one drop of a solution containing 1 mg. in 10 ml. of saline to tube or slide) will prevent the clumping, which interferes with the interpretation of tests. It has been found, further, that much higher concentrations of hyaluronidase do not interfere with any routine blood grouping procedures.

W. S. KILLPACK

PYREXIAL TREATMENT OF ULCERATIVE COLITIS

Sir,—In the early days of treatment of general paralysis of the insane by artificial pyrexia, a male general parietic was admitted to one of my wards at the County Mental Hospital, Ramhill. In view of his very poor general condition, complicated by long-standing ulcerative colitis, it was at first thought inadvisable to attempt pyrexial therapy, but at the insistent request of his wife a modified course of 'Pyrrifer' was given. It was observed with surprise that after the fourth intravenous injection the diarrhoea ceased. From that time onwards the stools showed satisfactory formation and there was no further evidence of colitis. Unfortunately the patient died a few months later as a result of his cerebral disease, and no conclusions could be drawn from the short period of apparent cure of the ulcerative colitis.

It was then brought to my notice that a male patient in another section of the hospital was suffering from ulcerative colitis of nearly two years' duration, and it was decided to study the effects of pyrrifer. The following notes have been extracted from his case sheet.

1934—May 19 taken ill with diarrhoea stools containing blood and mucus afebrile. May 26 Flexner organisms isolated from stools. Case notified to medical officer of health as bacillary dysentery. June 12 passing blood and mucus in stools. General condition failing. June 14 stools still show blood and mucus, no organisms of dysentery group now isolated. Febrile, 99–103°F, general condition poor. June 28 Bowel condition as before. Commonly febrile in evening. Slight improvement in general condition.

1935—April 26 diagnosed as chronic colitis, average of six motions daily, often containing blood and mucus.

1936—March condition unchanged. April 4 to May 11 course of twelve injections of pyrrifer producing on all occasions (except the third injection) temperatures of 103–104°F. No blood or mucus found in the stools after the third intravenous injection.

1937—Feb 17 no further diarrhoea. No change in mental state.

1941—Nov 12 reported diarrhoea. Nov 14 Schmitz organisms isolated. Chinosol exhibited for one month (details not given).

1942—Jan 15 clinically and bacteriologically clear, no evidence of colitis.

1947—March 28 attack of vomiting. Occult blood in stools. Presumably acute gastritis (no evidence of active colitis).

1948—April 13 reported to have loose stools. April 14 stools contained Sonne dysentery organisms but no blood or mucus. Treated with phthalylsulphathiazole emulsion. May 28 six swabs have been negative (no evidence of active colitis).

1950—May 31 no clinical signs of colitis.

In the ten years after leaving Ramhill Hospital in 1938 I was able to use this therapy in a few cases in another hospital. The results were reasonably good, but they were complicated by the fact that the pyrrifer available during the war years produced less fever. The ampoules had all been filled before September, 1939, and their potency in my opinion decreased with time. Using the fresh supplies obtained in recent years, the previous pyrexial response has been observed.

I can draw no definite conclusions from the small number of cases of chronic ulcerative colitis which I have been able to treat in the course of mental hospital

¹ Simpson S. L. *Post-grad med J* 1950 26 417.
² Lehmann H. *Lancet* 1950 i 1133.

practice. But it seems worth recording that in the case described the patient, despite two attacks of dysentery, has been free from any clinical signs of chronic colitis in the fourteen years following treatment with pyrifur.

I am indebted to Dr M G McColl, psychiatrist at Ramhill Hospital, for supplying me with the extracts of the case notes.

TROPHIC AND TROPIC

SIR,—Even if we do not completely agree with the opinion of Condillac and of some modern, logical positivists, according to whom Science is simply a well constructed language, there is no doubt that precise terms indicate precise conceptions, and thus the terminological chaos in contemporary endocrinology is not, unfortunately, a simple linguistic phenomenon. A discussion of terms is thus welcome.

"Tropic" means direction, and thus "thyrotropic hormone" means a hormone directed towards the thyroid and does not imply any further physiological conception. "Trophic" means nourishing and fixes an erroneous physiological conception, because this special anterior pituitary hormone stimulates the secretory function of the thyroid and not its nutrition. Deficiency of this pituitary hormone makes for hypoplasia of the thyroid and not for atrophy, these two terms are essentially distinct in Greek, atrophy indicating a nutritional phenomenon, and hypoplasia an organ inferiority, either congenital or due to disuse. We keep the Greek radicals in scientific terminology, not to show off our classical learning, but because Greek is a language which expresses with the greatest precision various aspects of phenomena. Thus, the terms "thyrotropic" and "gonadotropic" are more correct.

May I avail myself of this opportunity to protest against another terminological cause of confusion in endocrinology—the use of initials instead of well constructed terms? Why LH, ICSH, LTH, and other confusing constructions reminding us of military bureaucracy, and manifesting laziness and even slovenliness of thought?

London W 1

A P CAWADIAS

REVOLT AT KINGSTON

SIR,—You will not wish your pages to carry, each week, a letter in which Dr Morgan accuses me of untruth and I repudiate his statements as being inaccurate or biased. His letter last week answers none of my points and reveals an ignorance of the National Health Service which it is clear no fact or argument can alter.

However, he introduces a new principle to the health service which must be rejected. He suggests that appointment to the staff of a hospital by a regional hospital board does not make one a member of the staff of that hospital unless Dr Morgan agrees. From his letter it would appear that general practitioners who hold no appointment, but by invitation of the hospital management committee visit their patients in hospital, are members of the staff while consultants appointed by the board are not to be so considered. This strange doctrine clarifies and emphasises my point that no meeting of those actively working at the Victoria has ever been called.

The issue, however, goes far beyond that. The scheme for the reorganisation of the Kingston group has the full approval of all responsible for the hospital service of this country, and by this time next year the farcical position adopted by one fifth of the general practitioners in the group will be forgotten except for a lingering shame in their own minds.

Kingston Hospital, Surrey

D STARK MURRAY

MASS MINIATURE RADIOGRAPHY

SIR,—With reference to the letters from Dr Beynon (Nov 11) and Dr James (Nov 18), the no undressing technique was used in the mass radiography unit at the Royal Naval Barracks at Chatham in January, 1947. A survey of Admiralty civilian employees was undertaken at that time, and it was found that there were not enough chest covers for female examinees. They were therefore radiographed clothed, and the results were so good that since then I have not hesitated to use the technique whenever it has been more convenient to do so.

JAMES LEES
Surgeon Commander

Lee-on-Solent, Hants

REGISTRARS

SIR,—It would be as serious to underrate the value of the large non-teaching hospital to the registrar in training as to fail to appreciate the fact, already well expressed in your correspondence columns, that the registrar is an essential part of the staff of such a hospital. Without the experience of this type of appointment behind him, the new consultant, fresh from a registrar post in a teaching hospital, is likely for some time to lack the technical competence necessary for the proper charge of hospital beds.

If the Ministry's proposals become operative, in the scramble for the services of the few remaining registrars the non-teaching hospitals must not be sacrificed to the claim that all the training is done at the teaching hospitals.

County Hospital,
Whiston near Prescot,
Lancashire

J A MARTINEZ

SIR,—It took the Collings report to show how far the general practitioner had been separated from the hospital, and it has taken the Ministry's circular on registrars to show how far the hospital man has been separated from general medicine.

Dr Talbot Rogers, in his article of Nov 25, has thrown a very useful plank, hewn from the dead bulk of the circular, across the gap, but the serious imbalance in the arrangement and the qualities of medical service will not be corrected until the hospital doctor and the practitioner both vanish, and a doctor takes their place—until the houseman-registrar-consultant progression, based on a single point of distribution of professional service and a single standard of quality, applies in each field of medical activity.

When the activities of the local executive council, the regional board, and the hospital management committee, and of the school, industrial, and local health services are put into a single framework, based on area management under light Ministry control, we shall have an economy which will provide all the consultants and registrars we need, and some money to spare for over all development, health centres included.

W J CRABB
Secretary Fulham and Kensington
Hospital Management Committee

St Mary Abbots Hospital
London W 8

Public Health

Poliomyelitis

IN England and Wales notifications of poliomyelitis during the week ended Dec 2 were paralytic 90 (111), non-paralytic 38 (10), total 128 (130). The figures for the previous week are in parentheses. Uncorrected notifications for the corresponding week in 1947 and 1949 totalled 108 and 157.

Total uncorrected notifications for 1950 up to and including the week under review are 8379. The corresponding figures for 1947, 1948, and 1949 are 8927, 2272, and 6483.

Parliament

Domiciliary Physiotherapy Services

In the House of Commons on Dec 4 Mr KENNETH THOMPSON pointed out that some patients with, for example, heart-disease, or some elderly people with advancing infirmity, could not go to hospitals and clinics for physiotherapy. To meet their needs several regions had worked out contractual arrangements with outside agencies, such as district-nursing associations and private practitioners, to give the patients physiotherapy in their own homes. Such arrangements appeared to have had the blessing of the Ministry of Health. No fewer than 20 district-nursing associations were operating a mobile service of this kind. The regions had now received instructions which they interpreted as a direction to end their contracts with the district-nursing associations. Mr Thompson was uncertain whether the Minister of Health was seeking to cancel the present arrangements, to secure the fullest use of a skill in short supply, to ensure that the patient received adequate and proper treatment, or merely to economise. He had not been able to discover any complaints about the service given by the district-nursing association, which cost 9s per treatment in the Liverpool area. If a patient had to be taken to hospital for treatment the average cost for an ambulance would be, he thought about 20s a trip.

Mr ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, in reply, gave an assurance that patients who required physiotherapy in their homes on medical grounds would continue to receive it. But domiciliary treatment of this kind was, he insisted, a poor second best compared with that provided in a properly equipped hospital or clinic, and the Ministry would regard it as an exceptional case that should be treated at home. With old people, as with others the important thing was to give active treatment, and not to provide domiciliary treatment on a sort of permanent basis. The whole trend of modern medical treatment was to ensure the active participation of the patient as well as of the practitioner and specialist. Apart from the limited amount of equipment that could be provided with a domiciliary team, it was not economical that trained staff should be wandering about the countryside instead of providing treatment for several patients together in a clinic. In the experience of the Ministry with contracts of this sort there was a danger of a gradual growth of demand unwarranted on medical grounds. There must be reasonable control over how long the domiciliary treatment should go on, ensuring that patients should in due course continue their treatment in hospital. The Ministry had entered into discussions with the regional hospital boards on the best way of ensuring that there should be no loss of treatment for those who must have it at home.

QUESTION TIME

Hospital Boards and Publicity

Mr HECTOR McNEIL, Secretary of State for Scotland, said the representatives of the press regularly attended the meetings of regional hospital boards and the boards were grateful for the help and co-operation they received from the press. Whether the regional board minutes were placed in the public libraries was within the discretion of the boards, who took the view which Mr McNeil shared, that this was not the best way of securing publicity. They were adopting other means, and he was encouraging them to use those means to the full.

Tuberculosis Nurses

Mr ANSELM BEVAN stated that the numbers of nursing staff employed in sanatoria and tuberculosis hospitals were as follows:

	Full-time	Part-time
Trained nurses	2074	323
Enrolled assistant nurses	967	325
Student nurses	1372	—
Other nursing staff	1003	424
	5416	1072

Returns from local health authorities engaged as tuberculosis visitors at 360 full time and 1130 part-time

Mental-hospital Patients at

Mr S P VIANI asked the Home Secretary whether the Bill adopted for the inoculation of persons confined in hospitals who were rational in most respects and expressed objection to these injections and whether his regulations allowed such persons any right of refusal. Mr BEVAN replied: There are no regulations for inoculation of persons in mental hospitals, but if a patient expressed a rational objection to an injection it would not be administered.

Cuts in Numbers of Registrars

Mr J K VAUGHAN MORGAN asked the Minister of Health what was the present establishment of hospital registrars and senior registrars for the South West Metropolitan region, and to what figure these would be reduced when the proposed cuts were implemented. Mr BEVAN replied: About 320 in each case (including the teaching hospitals in the area). The new figures are respectively 151 and 83.

Mr NIGEL DAVIES asked the Minister whether he was aware that, whereas he had proposed that the number of hospital registrars and senior registrars in England and Wales should be cut from 2800 to 1700, it was proposed that the cut in the North East Metropolitan region should be from approximately 300 to 134, and what was the reason for this greater proportionate cut in this region. Mr BEVAN replied: The reduced number represents the share of the total which I think is appropriate to this region, taking into account its population, the number of consultants, the available training facilities, and the number of beds in that region as compared with the country as a whole.

Specialist Training

Mr DAVIES asked the Minister whether, in order to ensure adequate training and fair opportunities for doctors seeking to become specialists, he would arrange for a transfer system whereby registrars of non-teaching hospitals should spend a portion of their training period at teaching hospitals and whereby registrars at teaching hospitals should spend a proportion of their time at non-teaching hospitals. Mr BEVAN replied: I have already made this suggestion to hospital boards.

Expansion of Consultant Services

Mr E A HARDY asked the Minister why he did not expand the consultant services to the extent proposed in the pamphlet, *The Development of Consultant Services*, published by His Majesty's Stationery Office. Mr BEVAN replied: It is no use trying to increase the number of consultants faster than we can increase the beds and other facilities available to them.

Capitation-rate

Mr STANLEY EVANS asked the Minister whether he would revise his regulations so that general practitioners in the National Health Service were paid at a higher capitation rate in respect of the first 1000 or 1500 patients on their list, and at a lower rate as their lists became larger. Mr BEVAN replied: I have myself always preferred the idea of a graduated system which would discourage the accumulation of over large patient lists and encourage the better balanced practices. It is not always easy to translate it into fact, but I want to go into it very thoroughly with the profession in my discussions with them.

Kingston Victoria Hospital

Mr J A BOYD CARPENTER asked the Minister whether he had now considered the proposal of the British Medical Association that a public inquiry be held in connection with the dispute as to the future use of the Kingston Victoria Hospital and what action he proposed to take. Mr BEVAN replied: The future of the hospital has been very fully and carefully reviewed both by the regional board and by the Ministry of Health, as well as having been the subject of debate in the House of Commons. I certainly do not think that the proposed inquiry would either be appropriate or would add to our knowledge and I see no reason to intervene.

Mr BOYD CARPENTER: Is the Minister aware that one of the major reasons why local opinion feels that injustice has been done is that no opportunity has yet been given for local opinion to express itself directly to those responsible? Would not a solution such as that suggested by the British

practice

desecral Association give an opportunity, so far denied, for hasal opinion to express itself?—Mr BEVAN I do not believe in that there exists in Great Britain any better court of inquiry than the House of Commons itself, especially on a matter of this kind. If the hon. Gentleman thinks that the matter has not been adequately ventilated he can seek further opportunities.

Mr SOMERVILLE HASTINGS Would not the Minister agree that the opinion of experts in hospital management is more important than local opinion?—Mr BEVAN Yes, of course. This is the view which has been taken by the management committee and the regional hospital board, who have had all the facts before them, and, as I have said, the House of Commons as well. If the matter is not yet sufficiently ventilated I shall be most happy to recount the facts again.

Hospital Purchases

Mr ANTHONY GREENWOOD asked the Minister whether he would make a statement on the progress achieved in setting up a central purchasing organisation for hospital requirements.—Mr BEVAN replied Central contracts are placed for X ray equipment and films, laboratory and blood transfusion apparatus, spectacles, rubber goods, and certain scarce and costly drugs. Hearing aids are purchased under contract by the Post Office, surgical and orthopaedic appliances by the Ministry of Pensions and occupational therapy equipment and invalid tricycles by the Ministry of Works. I intend, as soon as practicable, to extend these arrangements to cleaning materials and hardware, bedding, cotton and woollen textiles, drugs and dressings and other common user goods. Net savings cannot be precisely calculated but are not less than £2½ to £3 million.

Notes and News

THE REGISTRARS

In a statement issued at the beginning of this week, the Socialist Medical Association calls for immediate withdrawal of the Ministry of Health's recent circular on registrars. "The Circular shows a total failure to understand the importance of the contribution made by registrars to the hospital service. The Circular fails because it treats the question of registrars in isolation, instead of as an integral part of the whole problem of staffing the hospitals, and the other medical services. The wholesale dismissal of registrars which it proposes will lead to an increase in waiting lists, diminish turnover, and in certain cases will lead to the closure of beds." The association takes particular exception to the proposal that registrars should join the Forces or the Colonial Medical Service, since it knows of no evidence that this country is over doctoring. The two main causes of the present disproportionate number of registrars are (a) failure to plan nationally the best use of medical manpower, and (b) the increasing difficulty of entry into general practice. The following are among the measures which, according to the association, are essential before present appointments are terminated: (1) a national policy on the medical staffing of hospitals must be formulated, (2) the surveys now being made of hospital establishments should be expedited, (3) as soon as (1) and (2) are completed, the necessary expansion of the consultant services should be speeded up ("where it is found that registrars are in fact doing consultants' work, consultant posts should be created and advertised"), and (4) hospital boards should be instructed to make no further appointments of part-time consultants. The association claims that the suggestion, contained in the circular, that general practitioners should act as part-time clinical assistants, to replace registrars, is clearly impracticable. Finally, the question of entry into general practice requires urgent reconsideration. Here the association proposes (a) that the maximum number of patients on each principal's list be reduced immediately to 3000, (b) that the Medical Practices Committee be reformed, (c) that the constitution of local executive councils be changed so that vested interests cannot prevent recognition of the real needs of the area, (d) that local authorities be encouraged to give more help in housing new general practitioners, (e) that first consideration be given to encouraging entry into practice in the under-doctored areas by inducement payments, (f) that there should be a retiring age for all practitioners in the National Health Service, and (g) that the right to immediate free choice of doctor should be restored. "We make these suggestions," the statement concludes, "without prejudice to our policy that fundamentally the solution to the problems of general practice is a salaried service based on Health Centres."

PARKINSON'S DISEASE

Mr Buchler* has been a sufferer from Parkinson's disease for 7 years and writes with the commendable object of helping his fellows. In his case the affection was possibly a sequel, after 21 years, to an attack when he was in China of "black" smallpox, in which he states that he lay comatose for three weeks. In view of the nature and object of the book he tells us very little about the various forms of treatment which he has received, and their comparative merits. "My favourite assortment (taken separately three times daily) is thirty drops belladonna tincture and one tablet hyoscine. I take 3 benadryl capsules daily." However, he advises a fortnightly visit to the doctor (and comments upon the antiquity of the literature supplied in the waiting rooms of many practitioners) one object of these frequent visits being to inquire after any new remedies. A good deal of advice is given upon the method of walking, and the procedure when a parkinsonian does his own shopping—but the author recognises quite candidly that the disabilities of the subjects of this disease are by no means uniform, and hence that the same method may not be suitable in all cases, certainly his recommendation to swing a stick, umbrella, or shopping bag as an aid to walking will not appeal to all. "I have always, strangely enough, found it easier to walk at night than in the daylight. It would be interesting to know how general this

1 See *Lancet* Nov 11 1950 p 537.
2 *Parkinson's Disease*. Advice and aid for sufferers of Parkinson's Disease and other physical disabilities. By WALTER BUCHLER. London: Walter Buchler 1950. Pp 70. 6s 6d.

perience is among parkinsonians. Undoubtedly it is true in some cases and one wonders whether the difference is due, at to any factor of light or darkness, but to some change in metabolism in the later hours of the day.

A large part of the book is taken up with rather platitudinous counsel about the conduct of life generally that would apply equally to the disabilities and limitations of normal old age. Thus the parkinsonian is advised upon the interest to be expected from investments, the choice to be made among the simultaneous programmes of the B.B.C., the characteristics of various newspapers, and the engagement of housekeepers, together with matters of more immediate import to him, such as the method of rising from the lavatory seat and the difficulties in the use of knife and fork. Various suitable hobbies are discussed, ranging from speculation on the Stock Exchange to the formation of a herbarium of weeds. The book has an excellent index such as is lacking in many books which have much greater need for it; a random glance at the items—astronomy, cabbage, crossword puzzles, marriage, socks, soles, soup, and so on—shows the breadth of the author's conception of parkinsonism.

Mr Buchler is a professional writer and no-one will object to his use of the disease from which he suffers to provide another book. He has written several millions of words on his typewriter, using one finger of each hand, a practice which he had adopted before the disease developed. He has thus solved one of the greatest problems—that of writing as he says, "even to sign one's name becomes a hard job."

In the autumn of 1948 he read in a newspaper of a fellow sufferer in this country who had gone to the United States for an operation on the brain to be performed by a surgeon at St. Louis and he decided to do the same himself although he does not appear to have known very much about the success of the operation on his fellow countryman. Every parkinsonian will applaud his wisdom in travelling "tourist" and thereby evading the manipulative difficulties of dressing for dinner. He goes on to give a topographical description of the *Mauretania*, in so far as the ship is accessible to passengers, and pays a tribute to the immediate help in every difficulty which he received from the staff. In New York his medical advisers decided against the proposed operation and he returned by air. Certainly if a man, travelling alone, can cross the Atlantic by ship and by plane with great enjoyment, his disabilities do not justify an operation of which the risks and effects are but little known. In conclusion one may congratulate the solitary traveller on his courage and his American friends on their wisdom in sending him home intact.

A NEW MEDICAL JOURNAL

The first issue of *Medicus*, which has just arrived from Pakistan, contains articles by European as well as local workers. Mr D. M. Stern, of the West Middlesex Hospital, discusses the use of veratrum viride in eclampsia. Dr M. A. Shah and Dr G. M. Awan, of Karachi, describe the treatment of trachoma with benzyl cinnamate and Dr A. R. Piracha deals with cardiac emergencies. The other articles include a note on Love as a Medical Problem in the historical section which is to be a regular feature. The editor Dr M. S. Quereshi, F.R.C.S.E., M.R.C.O.G. will have the help of an editorial board consisting of Prof. Shiyat Ali, Prof. Muhammad Basheer, Prof. Y. M. Khan, Prof. N. A. Quraishi and Prof. Muhammad Yusuf. Dr Quereshi says that *Medicus* is intended to satisfy the great need for a really good medical journal in Pakistan. Judging by the first issue, it is likely to succeed.

BRISTOL FASHION

BOOKLETS on local health services are often as indigestible as cold suet pudding and about as dispiriting. In tempting his fellow citizens to know and use the amenities of the Bristol health department Dr R. H. Parry, the medical officer of health, shows the resource and sagacity of a Mrs Beeton garnishing his plain dish of facts with such well-chosen pictures, and such an appetising display of good paper and type that all must relish it. The health services in Bristol are presumably of the same order as those elsewhere, but this book reveals the pride the health department takes in them and the thoroughgoing efforts made to tell people about the care to which they are entitled. They are told

who is responsible for every section of the department's work, and where to apply for help in any necessity or emergency to do with health. The pictures interpreting the text have been gathered from various sources, including *Illustrated*, *Topical Press*, and the *Bristol Evening Post* and *Evening World*, and they have what is called in the trade "human interest." The danger of human interest is sentimentality, but these pictures avoid it. They bring to mind that Bristol is a seaport that people live in good houses and bad, that children are by nature confident, that old people like company, that a dentist at work can provide a satisfying aesthetic pattern—anyhow for the looker on. They are, in current slang, just the job.

DEATH OF MR BARTLETT

In *Did Adelaide Bartlett*?¹ Gordon Gwyn (a pseudonym concealing the identity of a practising anaesthetist) picks up the thread of an unsolved mystery of the '80s, and attempts to unravel it in the light of modern medical knowledge. In a manner by turns light hearted and dramatic, he unfolds the story of the strange marriage of immature Adelaide de la Tremoville to pompous Edwin Bartlett with his odd ideas about the marriage bed. The familiar triangle is completed by a particularly ingenuous cleric, and the story moves to its climax with the strange but expected death of the husband. The manner of his death clearly needs an anaesthetist to explain it, and Gordon Gwyn discusses ably the evidence at the trial and gives his own conclusions. The main facts are taken from the authentic records, and the manner of presentation is up to the standard of the better mystery stories of fiction.

"YOU AND YOUR HEART"

FIVE American authorities have collaborated to produce a book whose aim is to give the layman a concise non technical explanation of the heart and circulatory system, believing that in this way they may prevent over anxiety in the patient with heart-disease and in his relatives, and put at rest the fears of those in whom heart trouble is only imaginary. They also give some general rules about the mode of life to be adopted by the patient, always with the emphasis on encouragement and optimism. Finally they discuss prevention, and give a brief account of the most pressing problems in the care of patients with cardiovascular diseases and the American organisations attempting to solve them. They cover the anatomy and physiology of the circulation, congenital coronary, and rheumatic heart-disease, high blood-pressure, and diseases of the peripheral blood vessels.

It is difficult to know how much a book of this type however clearly and simply written, would help the layman of this country. In the introduction doctors as a group are described as "unable or unwilling to explain clearly, in simple terms, some of the things that patients most want to know." If this is so perhaps it is the doctor rather than the patient who should read this book.

MAN-EATING SHARKS

Mr V. M. Coppleson of Sydney, states that each year about 4 or 5 attacks are made by sharks on human beings on the coast of Australia.² There have been 77 attacks on bathers in the last thirty years and 33 on pearl divers in the ten years 1926-36. There is also evidence that sharks sometimes eat dead bodies. Attacks have often been made on manned rowing boats and on such occasions the shark is apt to lose a tooth by which the species (always the Blue Pointer in Australian waters) can be identified. Sometimes human limbs have been recovered from sharks' stomachs after the lapse of more than a week and have then shown strangely few signs of digestion.

Thirteen years ago the experiment was made of laying a long net off the beach each evening and hauling it away by trawler each morning. Areas so meshed have since been completely free from attacks by sharks on men. Though the risk to bathers is numerically infinitesimal these accidents, as Mr Coppleson says, are horrible and the victims are usually people full of life and youthful vigour.

M. F. Yorke

National University of Ireland

Dr John Dunne has been elected to the professorship of psychiatry at University College, Dublin

Dr Dunne graduated M.B.N.C.I. in 1922 and he also holds the D.P.M. and D.M.D. After qualifying he held the post of assistant medical officer at Grangegorman Mental Hospital Dublin till in 1930 he was appointed R.M.S. at Sligo Leitrim Mental Hospital. He returned to Grangegorman Hospital to take up his present position as R.M.S. there in 1937. He has published papers on the malarial treatment of G.P.I. and on dementia praecox.

Royal College of Physicians of Edinburgh

Sir David Henderson has been re-elected president of the college for the ensuing year and Dr W. A. Alexander vice president. The following office bearers have been elected:

Members of Council: Dr W. A. Alexander Dr D. J. A. Kerr Dr D. N. Nicholson, Dr R. M. Murray Lyon Dr J. G. M. Hamilton and Dr T. Anderson treasurer Dr J. Alastair Bruce secretary Dr J. Halliday Croom hon. librarian Prof. D. M. Lyon registrar Dr Croom

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Dec 4, with Mr Walter Galbraith, the president, in the chair, the following were admitted fellows of faculty *qua* physician:

J. O'D. Alexander Thomas Chelvarajah J. S. Creighton A. S. Douglas Ravindra Motchand Kapadia, Joan B. Landsman, Syed Abdul Mannan, G. C. Provan W. G. Whyte

Irish Conjoint Board

On Dec 1, the following candidates were admitted licentiates in medicine and midwifery, having passed the final examination of the board:

Eleanor A. Bolger Alice Boushel J. P. Cahill James Connolly, Dorothy J. Davis M. J. Foley Carmel P. Gibson V. J. Haslan Mabel Jackson Mary J. McCann Helena M. McManus, M. P. McPartlin Sheila Moriarty, Maureen B. O'Gorman A. P. O'Kelly, M. P. O'Reilly Sheelah K. O'Shea R. A. Power S. J. Raverty Alexander Rudnick W. E. Rutherford Dymphna E. Sharkey W. S. Snow C. M. Watson Avril M. Webb J. R. White J. E. Whyte C. E. Wilson

Industrial Injuries Advisory Council

Prof. R. E. Lane, F.R.C.P., has been reappointed, and Sir Hugh E. Griffiths, F.R.C.S. and Prof. J. M. Mackintosh, F.R.C.P., have been appointed to the council.

German Medical Congress

A meeting of the Deutsche Gesellschaft für innere Medizin will be held at Wiesbaden from April 2 to 5. Further information may be had from Prof. Fr. Kauffmann, (16) Wiesbaden, Städtische Krankensanstalten.

Kingston and Malden Victoria Hospital

At the end of last week Kingston Group Hospital Management Committee reaffirmed its decision to convert this hospital into a gynaecological unit. The general practitioner staff have refused to act on notice to quit the hospital (see *Lancet*, Nov 11, 1950, p. 527) and they have been having the entrance picketed. (See also p. 829.)

Sight Tests

To prevent unnecessary sight tests, the Minister of Health has asked ophthalmic medical practitioners and ophthalmic opticians taking part in the supplementary ophthalmic services to ensure

before they test a patient's sight that the name and address of the optician who supplied the patient's previous glasses and the date of the last sight test, are entered on the application form and that sight is not tested without the permission of the Ophthalmic Services Committee if it has been previously tested within the preceding 12 months except when in their view the need for a further sight test appears to be urgent or the patient's G.P. has been informed that the patient should have a further examination within 6 months of the test.

Northern Regional Hospital Board

Mr James South has been appointed chairman of the Scottish board in place of Mr Donald Macpherson, who has resigned.

Institute of Psychiatry

On Wednesday, Feb 14, Dr Manfred Bleuler, professor of psychiatry in the University of Zürich, will give a lecture at the institute, Maudsley Hospital, London, S.E.5, on Acromegaly and Acromegaloïd Psychiatric and Genetic Aspects.

Hearing-aids

At a symposium on this subject to be held on Wednesday, Jan 10, at 6.30 P.M., at the London School of Hygiene, Keppel Street, W.C.1, by the British Institute of Radio Engineers, Mr E. R. Garnett Passeur, F.R.C.S., is to speak on the clinical aspect of deafness and the possibilities of its alleviation medically and by hearing aids.

Conference on Social Medicine

The social medicine research unit of the Medical Research Council proposes to hold a conference in London on problems of research, with special reference to method, on April 25 and 29. Professional workers in the various fields of social medicine can obtain further information from Dr J. E. Morris, S.M.R. Unit Central Middlesex Hospital, Acton Lane, London, N.W.10.

Care of the Old

Speaking at the opening of an old people's home at Balnagask, Aberdeen, on Dec 6 Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland, said that lately it had been calculated that ordinarily a general practitioner averaged about 3 visits per annum to a patient's home and just under 3 visits per annum by the patient to the surgery, whereas for elderly patients the average was 7½ visits to the home and 2½ to the surgery. He continued, however, "Too often when considering the needs of the elderly, we put the cart before the horse. Too often, when we think of health matters, our minds turn first to hospitals and second to hostels and only third to the patient's own home. Actually, though a hospital does excellent and very necessary work, a hospital is the last line of defence, the fact that a patient has become ill enough to require admission to hospital may be taken as an indication that the health promoting and disease preventing services have been unsuccessful, and a community that requires very large or very numerous hospitals is an unhealthy and miserable community. Let us realise, quite definitely that the emphasis must be placed the other way. From the point of view of the happiness of their own individual, most people are infinitely happier in their own homes than elsewhere, and of those who become too frail to live an independent existence in their own homes, the vast majority are much happier in hostels such as Balnagask than in a hospital. Fortunately economic factors line up with the happiness of the individual—£2 a week at home and happier or £3 10s a week in a hostel, or anything from £8 upwards in a hospital."

The new I.C.I. film catalogue contains a list of all films produced by the company, including 25 for medical audiences only. They may be borrowed free of charge from the I.C.I. film library Bolton House Curzon Street, London W.1, from which copies of the catalogue may also be obtained.

THE FUTURE OF THE PRACTICE OF MEDICINE*

A LESLIE BANKS

M A Camb, M D Lond, F R C P, D P H

BARRISTER AT LAW, PROFESSOR OF HUMAN ECOLOGY,
UNIVERSITY OF CAMBRIDGE

It was, I think, Winston Churchill who said that to look forward one must be able to look back. As one who has studied either actively or passively the conduct of medical practice in this country over the past twenty-five years, and has lately been inquiring into the problems of rural practice in East Anglia and the West Country, it is my considered opinion that the standard of medical care both in hospital and in general practice is infinitely better today than it was formerly.

Take for example, the various aids to diagnosis. Some twenty years ago clinical bacteriology and biochemistry were in their infancy and the full-time specialists in these branches were still pioneers in the teaching hospitals. In many hospitals the work was done by a technician supervised by a part-time pathologist who might be either an assistant physician to the hospital, a general practitioner in the town, or the local medical officer of health. X-ray departments in the smaller hospitals were commonly run by the X-ray sister, who might also be the outpatient and casualty department sister. A part-time radiologist would visit once or twice a week. A blood transfusion was still a major event and the full-time practice of anaesthetics was usually limited to the big hospital centres. Registrars were few, and much was left to the house surgeon or house physician.

I have still the most vivid recollection of two resident medical officers, one aged 24 and the other aged 22, attempting to operate on a difficult mastoid at a busy provincial hospital. The younger R.M.O. gave the anaesthetic, his first since qualification, and emerged from under the towels to tell his colleague that the patient was in a bad way—only to find that the latter had opened the lateral sinus. The patient made an uncomplicated recovery.

On another occasion no member of the surgical staff of this hospital was available to operate on a fulminating appendicitis in a fat patient, and the young R.M.O. had to do this with the aid of the theatre sister. By way of contrast, when the young man returned to his own teaching hospital a fairly skilled operator, he found that house surgeons were not allowed to make even an incision for the first three months of their residency.

Outside the hospital equally great contrasts were to be found. General practitioners varied in quality from those in the slum areas who referred every case to hospital to those in rural areas who were prepared to tackle everything from removal of the gall bladder or radical mastectomy to a tennis elbow. Poor law medical officers were still paid at the rate of £40-100 per annum, and for this sum might be expected to supervise the entire sick of a poor law infirmary, including the practice of midwifery, the care of children, and the septic block. The "operations book" of the infirmary of a country workhouse sometimes provided lively play for the imagination.

This uneven picture was changing rapidly during the 1930's and the outbreak of war in 1939 heralded the break-up of the earlier system. The advances of the past few years are too well known to require detailed description. The antibiotics, advances in blood transfusion and anaesthesia, and the development of teamwork in hospital have made "impossible" procedures matters of everyday practice. To give only one example, an article has recently appeared in the *British Medical*

Journal describing a series of cases in which mitral stenosis had been relieved by the insertion of a finger into the left auricle and stretching the stenosed valve. And thus at a time when the standard textbooks still mention the application of leeches! Dramatic clinical advances tend to obscure the effects of public health measures, but these are shown in many ways. The isolation hospitals built only a few years ago to accommodate 100 or 200 patients may now have a yearly average of 12-20 cases. Maternal and infant mortality and the number of stillbirths continue to fall rapidly, and we have not yet seen the full effects of better housing, improved nutrition, and more enlightened teaching in physical and mental health.

In 1860 Oliver Wendell Holmes wrote a series of medical essays,² in which he said

"There are, of course, in every calling, those who go about the work of the day before them, doing it according to the rules of their craft, and asking no questions of the past or the future, or of the aim and end to which their special labour is contributing. These often consider and call themselves 'practical men'. They pull the oars of society, and have no leisure to watch the currents running thus or that way. The theorists and philosophers attend to them. In the meantime, however, these currents are carrying the practical men too, and all their work may be thrown away, and worse than thrown away, if they do not take knowledge of them and get out of the wrong ones and into the right ones as soon as they may. It is not only going backward that the plain practical workman is liable to, if he will not look up and look around; he may go forward to ends he little dreams of. And so with subtler tools than trowels or axes, the statesman who works in policy without principle, the theologian who works in forms without a soul, the physician who, calling himself a practical man, refuses to recognise the larger laws which govern his changing practice, may all find that they have been building truth into the wall, and hanging humanity upon the cross."

At no time in the history of our ancient profession has it been more necessary for the "practical man" to look up and look around. The armamentarium of the doctor is being added to every day. The diseases that he treats are undergoing modifications visible to all. The changes in the people who form his patients and in the conditions under which he works are less obvious.

CHANGES IN PATIENTS

Perhaps the most obvious change in the patients is their increasing age. Already more than 10% of the population of this country are over sixty-five years of age, and this proportion is increasing rapidly. Therefore the patients of the future may be expected to include a much larger number of chronic and degenerative diseases and the frail and infirm.

Geriatrics is a term to which it may be possible to attach undue emphasis. When a man reaches the age of sixty-five he will count himself fortunate if he has more than fifteen years to live. What does he want during those years? Is it reasonable comfort, food, shelter, and relief from the more serious disabilities? Or does he expect to be entirely reconditioned like a second-hand motor car? Many people both inside and outside the medical profession are busily engaged in pointing out that the country can afford to spend only a certain amount on medical services. Their proposals as to how this money should be allocated are not always clearly expressed, but all will agree that any proposal to spend large sums of money on elaborate services for the care of the aged needs careful scrutiny if it is to be at the expense of the young. Recent research in the Department of Experimental Psychology of Cambridge University has shown that the process of ageing begins

Care of the Old

Speaking at the opening of an old people's home at Balmagask, Aberdeen, on Dec 6, Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland, said that lately it had been calculated that ordinarily a general practitioner averaged about 3 visits per annum to a patient's home and just under 3 visits per annum by the patient to the surgery, whereas for elderly patients the average was 7½ visits to the home and 2½ to the surgery. He continued, however, "Too often, when considering the needs of the elderly, we put the cart before the horse. Too often, when we think of health matters, our minds turn first to hospitals and second to hostels and only third to the patient's own home. Actually, though a hospital does excellent and very necessary work, a hospital is the last line of defence, the fact that a patient has become ill enough to require admission to hospital may be taken as an indication that the health promoting and disease preventing services have been unsuccessful, and a community that requires very large or very numerous hospitals, is an unhealthy and miserable community. Let us realise, quite definitely, that the emphasis must be placed the other way. From the point of view of the happiness of the individual, most people are infinitely happier in their own homes than elsewhere, and of those who become too frail to live an independent existence in their own homes, the vast majority are much happier in hostels such as Balmagask than in a hospital. Fortunately economic factors line up with the happiness of the individual. £2 a week at home and happier or £3 10s a week in a hostel, or anything from £8 upwards in a hospital."

The new I.C.I. film catalogue contains a list of all films produced by the company, including 25 for medical audiences only. They may be borrowed free of charge from the I.C.I. film library, Bolton House Curzon Street, London W.1, from which copies of the catalogue may also be obtained

disappointed. Where can they go? The Armed Forces, the Colonial Service, and the Colonies will absorb some, but the Colonial demand will diminish because they are training their own men on the spot.

It is vaguely assumed that the men not required in the hospital world will enter general practice. Is this a safe assumption? And what attraction is there in general practice for a man who has spent a number of years in hospital unless there is a likelihood of a hospital appointment going with the practice? Apart from this, are there in fact many openings in general practice? The answer is No, and the reasons are not hard to find. First and foremost the size of the general practitioner's "pay packet" in the National Health Service depends on the numbers on his list. "The more" so to speak, "the merrier" and so men must aim at quantity and not quality. Next comes the fact that many elderly general practitioners cannot afford to give up. The value of their savings, if any, has declined and they cannot claim a pension under the new service. Thus a number of men (one estimate is as high as 6000) of ages ranging from fifty-five to over eighty must continue to work. Many other factors also come into play. If a man is to retire where is he to live? If he cannot get a house elsewhere he will stay where he is.

Meanwhile the supply of young doctors continues undiminished and medicine continues to be regarded by fond parents as sufficiently attractive to justify heavy sacrifices for their sons and daughters.

A DECLINE IN QUALITY?

The dangers of the present position are not, therefore, confined to a temporary and non-recurrent crisis but threaten the whole future of the medical profession and the practice of medicine. Not the least of those dangers is the possibility that the State may be forced, on the grounds of economy, to make cuts in hospital staffs which will have the effect of imposing rigid "establishments" and a hierarchy on service lines which will ramp or sterilise new developments.

It is in the maintenance of the quality of medical care that the most urgent consideration is required. The practice of medicine, like the law, has been built on the traditions of independent practice wherein competition and the prospect of financial rewards have stimulated each man to do his best for his patients. "Myself," said Jeff Peters,⁸ "I never believed in taking any man's dollars unless I gave him something for it—something in the way of rolled gold jewelry, garden seeds, lumbago lotion, stock certificates, stove polish, or a crack on the head to show for his money." Removal of the personal incentive will, for many men, take off the fine edge of skill. It can be argued that most people in this country are salaried. That is true, but most people in this country do not need to work always at concert pitch, nor do they carry the lives, or more important, the health and happiness of their fellows as their daily responsibility. Quite apart from this question of incentives is the maintenance of accuracy under pressure. Perhaps the most urgent clinical need at present is the early diagnosis of malignant disease. Who is the more likely to achieve this? The man with 5 patients waiting to be seen or the man with 35?

WHAT DOES THE GENERAL PRACTITIONER WANT?

Doctors usually make poor administrators, mainly because they have never learnt to express themselves in terms which the layman can understand. The need which all doctors feel for a closer integration between the general practitioner and the hospital is a good example. Very few people outside the medical profession understand the real nature of the problem, and indeed many doctors have only a hazy notion.

First what does the general practitioner want? Is he to be a good all-round practitioner, or does he want to be a specialist? If the former, then his needs are clear and can be simply expressed in one word—time. Time to examine his patients properly, time to read, time to think, and time to discuss recent advances with his colleagues.

It is possible to gain time in various ways—in spite of Henry Ford's dictum that time is the only commodity that if wasted cannot be salvaged. The health centre can be dismissed as a practical consideration, since, apart from expense, no one has yet a clear conception of what it should be, nor have doctors and dentists yet signified their willingness to work in these centres. This is perhaps just as well, for the isolation of general practitioners in health centres divorced from their colleagues in consultant practice would not be in the best interests of clinical medicine. By sharing clerical, nursing, and housekeeping assistance much of the drudgery of general practice could be eliminated. That is the essence of group practice. Time might also be saved by discarding firmly non-medical and irrelevant work. The general public would soon learn that this is to their advantage.

Alternatively does the general practitioner want also to be a specialist? If so how does he propose to get about it? The acid test for any general practitioner who considers that he is equipped to specialise is, presumably, to ask himself whether his colleagues would entrust their wives and children to his care in this specialty.

In order to extend his responsibilities the practitioner must have ancillary aids to diagnosis. There has been much loose talk both within and outside the medical profession about direct access by the general practitioner to X-ray, pathological, and physiotherapy departments in hospitals. At the request of the Nuffield Provincial Hospitals Trust some of my colleagues and I have been inquiring recently into these possibilities, and although our inquiries are not nearly completed some facts are already emerging. First it is clear that the specialist departments in some hospitals cannot cope adequately with their own inpatient and outpatient demands, so that in the absence of new building it would be physically impossible to extend the resources of these departments to those outside the hospital. Even where the consultants and specialists are willing and the facilities are available such safeguards as an appointments system, a written report by the doctor, and limitation of the investigation to certain categories will be necessary. Thus everyone agrees that the general practitioner should be able to obtain an X-ray report in pregnancy or for a doubtful chest. What more does he want? Fractures? If so is he prepared to treat them? Peptic ulcer? If so is he going to assess the progress of the ulcer by X-ray examination every two months? Kidneys and gall bladder? If so, what does he propose to do when abnormalities are found? Similarly with pathological investigation. Blood counts and pregnancy diagnosis tests are essential for the general practitioner in certain instances. But who is to decide what other types of investigation the general practitioner needs and how much responsibility is he prepared to carry?

Opinion among the consulting staffs is by no means united. Many physicians and surgeons feel that if they are to treat a case they would like to see it from the beginning and not after it has been handled by someone else. It would be harmful to all for the general practitioner to carry the patient for a certain distance and dump it on the consulting staff with a request that they should be responsible from then on.

Again, general practitioners want, and rightly, hospital experience. Are they to obtain this as clinical assistants, or do they expect to have beds of their own in hospital?

in the early thirties. Is it not to the postponement of the ageing process that we should devote our main efforts?

The effects of improved social conditions on health are already visible in the clinical field. Such diseases as chlorosis have long since joined the historical section of the textbooks, but what of the conditions such as mucous membranous colic, viscerotaxis, and the other neuroses so common in young women only a few years ago? How often are really serious malnutrition and septic skin conditions seen in children today? How many grossly deformed rheumatoid arthritis cases are now seen as compared with twenty years ago? Where is the desperately ill young rheumatoid arthritis patient? It is clear that sensible clothing, teaching of correct posture in childhood, fresh air and exercise, and improved working and housing conditions are producing young men and women of incomparably better physique than was the case twenty years ago. These young people are, in spite of the jibes about football pools and strip cartoons and the like, better educated and more alive to health measures than their forebears. It is doubtful whether it will be possible in the future for a surgeon to earn, like one of my former chiefs, a reputation for breaking down adhesions by manipulation without an anaesthetic. "The secret, my boy," he used to say, "is stiffly starched cuffs and loose cuff links." Needless to say he was a man of outstanding personality.

The real problems of the future lie in the middle aged groups. The speed and stress of modern life tell particularly on those holding executive responsibility, whether as managing director or works foreman. It is already clearly shown in the incidence of peptic ulcer, which in 1947 accounted for eight out of every thousand people ill during an average month and caused twenty six out of each thousand days of incapacity.³ Coronary thrombosis, and psychosomatic disorders of the skin, circulatory and digestive systems may be expected to take the place of the more simple functional symptoms of earlier generations.

A MORE COMPLEX MEDICAL ORGANISATION

The care of the patient in the future will require a far more complex organisation than in the past. Team-work and specialisation in hospital will require to be co-ordinated with care in the home and at work. The need to treat the whole patient with due regard to the psychological aspects of his disease requires full investigation of his social background, and the almoner and other social workers are now indispensable members of the medical team. Much valuable hospital accommodation is at present wasted because patients are admitted unnecessarily or stay too long. It is probable that the general hospital of the future will become a highly specialised diagnostic and treatment centre with patients transferred to simpler accommodation for after-care. This comment applies particularly to the long stay cases.

The treatment of carcinoma of the rectum at St Mark's Hospital in London provides a good example of the results of team work. The surgical staff of this hospital have developed the method of synchronous combined excision of the rectum whereby two expert surgeons work together one through the abdomen and the other from the perineum. In 1939 the operability rate (i.e. resectability) was 63%. In 1949 it was over 96%. The average at other hospitals throughout the country is of the order of 30%. The operative mortality for cancer of the rectum is shown by the British Empire Cancer Campaign figures to be from 15 to 50% in various hospitals. At St Mark's Hospital it was in 1949, only 9%. This figure includes all the surgeons there and all the "bad risk" cases.⁴

CHANGES IN THE MEDICAL PROFESSION

While the weapons of attack upon disease and the reactions of the patients have changed, it is the medical profession which has undergone the most startling revolution. Within the past two years this traditionally conservative profession has been placed, as it were, in a gigantic centrifuge which is still spinning rapidly. The effects are not yet fully visible, but they are clearly disruptive and may be catastrophic.

Take first the consultants and specialists. Until two years ago the would-be consultant achieved his objective in the teaching hospital by a combination of ability, tenacity, and luck. The non-teaching hospitals were staffed by those who had been through the teaching hospital mill or who had graduated from general practice. The senior physician of one large provincial teaching hospital, a man respected and loved by all, began his career by purchasing a derelict practice in the town from a drunkard for a few pounds. Slowly and by sheer ability and integrity he has climbed to a position of eminence.

What is the picture today? First comes the desperate scramble for a higher qualification. It is of interest to note that of the many hundreds who sat for the M.R.C.P. (London) 35 passed in May of this year and 47 in February. Next comes the scamper for the training ladder. Those who succeed in getting both feet on this expect to climb rapidly until at the mature and experienced age of thirty-two they may assume, by virtue of a "contract," the responsibilities of an Osler, a Moynihan, or a Bland Sutton. Meanwhile the channel of recruitment from general practice has been completely blocked.

It is not surprising that the young men fresh from the medical schools all want to be consultants. In the past two years contracts (*quid significat, sonat haec vox?*) have been issued to consulting staffs of all hospitals. Most of these men fall between forty-five and fifty-five years of age. This means that for the next ten to fifteen years there are going to be very few vacancies. There are no national estimates, and a leading article in *The Lancet*⁵ has emphasised the urgent need to publish the facts for England and Wales and to form a policy thereon. The results of my own inquiries agree substantially with the findings of the recent Scottish Survey.⁶ Thus in one large hospital region—mainly industrial—it has been estimated that for the next ten years the consultant requirements in all branches will be 5 for each year and after that 10 a year. If this picture is typical of the whole country, the requirements of the fourteen regions in England and Wales will amount to 70 vacancies each year for the next ten years and 140 a year at the end of the ten year period. If a specialist "establishment" of consultants and senior hospital medical officers of 7000 (which is more than the number now in post) is accepted as not unreasonable, a wastage of 3% per annum would result in a total of 210 vacancies per annum. The truth probably lies somewhere between these two estimates—i.e. between 70 and 210 vacancies each year. These figures take no account of dilution by non-medical personnel, lower or specially created grades, or a resuscitation of the general practitioner specialist. At present about 1539 senior registrars, 1477 registrars, and 790 junior registrars are employed in hospitals in England and Wales. Many of these young men are going to be

⁵ *Lancet* 1950 i 1157.

⁶ The Ministry of Health in Circular H.B. (50)106 dated Nov. 6, 1950 has now laid down that the number of training posts (i.e. registrarships) is not to exceed 600 senior registrars and 1100 registrars. The Ministry's action is based on the estimate that the number of appointments available to senior registrars who complete their training in England and Wales is unlikely to exceed 150 a year for some years to come. This includes not only consultant and senior hospital medical or dental officer appointments necessary to make good wastage through death or retirement but also a proportion of additional posts and openings in other services and overseas as well as hospital in this country.

⁷ *Lancet* 1950 i 1165.

with frank pernicious anemia have not been included for they present no serious diagnostic problem

EARLY CLINICAL MANIFESTATION

Subacute combined degeneration of the cord presents in various forms. We shall not here describe the pictures which arise from degeneration in the white matter of the cord and in the peripheral nerves. Suffice it to say that sometimes the signs may suggest such diverse conditions as spinal compression and peripheral neuritis.

In advanced cases the diagnosis is usually obvious and confusion is unlikely unless the blood picture is normal or nearly so. Careful inquiry may, however, elicit a history of dysesthesia affecting all four limbs at an early stage, before the patient recognised the insidious approach of illness. He complains less of these as time goes on—possibly because they become less obtrusive, possibly because his incapacitating symptoms assume such importance.

The patient with subacute combined degeneration often seeks medical attention during the early stages. Because his complaint is vague and does not indicate the impending gravity of his condition, a diagnosis of neuritis is usually made and he is treated with vitamin B₁. Indeed these symptoms may be due to degeneration of the peripheral nerves in subacute combined degeneration. The presence of demyelination of peripheral nerves in this disease was demonstrated by Greenfield and Carmichael (1935). The reduction of myelin was of the same type as in alcoholic neuritis. This diagnostic difficulty may be illustrated.

Case 1—A man, aged 63, had noticed that his finger-tips became unusually cold during the last two winters. Twelve months ago his fingers had felt numb and puffy and were clumsy. During the last six months his lower limbs had felt stiff. More recently, on rising in the morning, his legs had felt numb from the waist down. When kneeling he had felt as if he was kneeling on bare bone and there had seemed to be tight bands round his knees.

Examination—In spite of the obtrusive nature of the dysesthesia, little was found on examination. There was slight ataxia of the lower limbs. Power, tone, and reflexes appeared normal. Vibration was not felt over the knees and ankles or over the sacrum and lumbar spinous processes. This sensation was also diminished over the hands. The threshold for two point discrimination was slightly increased. There was no muscular tenderness. The mucosa of the tongue was slightly atrophic. The cerebrospinal fluid was normal, and a histamine test-meal showed achlorhydria. The peripheral blood and sternal marrow were normal, but the patient had been receiving intermittent liver therapy, which had been instituted without examination of the blood.

Fig 2—Subacute combined degeneration of the cord with no blood changes (case 3). Biopsy specimen of mucosa of body of stomach showing thinning, disappearance of chief and parietal cells and metaplasia to columnar epithelium of intestinal type with plentiful goblet cells. There are no excess wandering cells in supporting stroma. (Stain as in fig 1) ($\times 105$)

Fig 1—Biopsy specimen of normal mucosa of body of stomach. Section extends down to muscularis mucosae. Superficial quarter of mucosa shows mucus-secreting surface epithelium extending down into shallow pits. Rest of section is made up of tubular gastric glands with darkly staining pepsin-secreting chief cells and lightly staining acid-secreting parietal cells. (Methyl violet-orange G Ponceau-phloxine and methyl green.) ($\times 105$)

there is a well-defined picture of pernicious anemia in the peripheral blood. It is the opinion of many observers, and it is also our opinion, that subacute combined degeneration of the cord may occur with no significant changes in either the peripheral blood or the bone-marrow.

To achieve early recognition of those cases of subacute combined degeneration of the cord where the neurological manifestations are but slight or equivocal, and where the blood changes are minimal or inconclusive, it is necessary, besides detailed neurological examination, to make full use of every additional procedure which may shed light on the diagnosis.

It is the purpose of this study first to emphasise the proper assessment of dysesthesia referred to the extremities, secondly to discuss the early changes in the bone marrow in pernicious anemia, and finally to add a further aid in diagnosis—gastric biopsy. As regards gastric biopsy, it has been our experience that all patients with subacute combined degeneration of the cord and/or pernicious anemia show considerable atrophy of the mucosa of the body of the stomach associated with histamine fast achlorhydria. The nature of the biopsy fragments thus serves as a valuable guide to the correct diagnosis.

Thus at the outset we may define our attitude towards certain points which have been the subject of controversy—whether subacute combined degeneration of the cord may be associated with the presence of free hydrochloric acid in the gastric contents, and whether any form of anemia other than the pernicious type may be present.

We believe that the cause is one which tends also to lead to pernicious anemia and in which histamine fast achlorhydria is constantly present. These are the only cases which we see in Australia. If the term is used in this sense it symbolises a rigid concept. If, however, the term is used in a literal sense, it may include degeneration of the white matter of the cord due to other causes. In these cases free hydrochloric acid may be present in the gastric contents, but only older reports suggested that such cases exist (Grinker 1926). However, we have no personal experience of such cases and believe that they belong to a different group. Secondly, if microcytic anemia be present, we believe that it is due to other causes commonly leading to anemia of this type and not directly associated with the disease.

The cases selected are, in the main, those referred to one of us (E. G. R.) for neurological consultation. Cases

are to have beds in hospital, what kind of patient is to be treated there? Only the doctors themselves can answer these and similar questions, and until they make up their minds they cannot expect the layman to do it for them.

The question of access to hospital is a particularly difficult one. The day of the single handed consultant and specialist in hospital is over. He is a member or the head of a team. This is well shown in such a specialty as diagnostic radiology. In one large London teaching hospital the head of the department deals almost entirely in medical work. He has, in his department, one assistant specially trained in neurological work, and another in orthopaedic work. There is also a tendency to specialise within this department in gastro intestinal or chest examinations. Accurate radiology depends on meticulous technique which requires long experience, and it is difficult enough for the specialist to keep abreast of recent advances such as angiocardiology and the possibilities of examination with more selective contrast media. It is still more difficult to keep abreast of all recent advances in medicine and surgery and to pass that information to the busy general practitioner. It is clear that the days of Abernethy are over and that the Pooh bah is an anachronism.

It is also true that the practice of medicine cannot follow the artificial administrative divisions of a National Service. The general medical practitioner's work lies mainly outside the hospital, but he must be able to go in and out as he wishes—not in order that he may obtain a "contract" but because he is vitally interested in the patient that he sends in. Alternatively he may possess real ability in some special subject which, for the benefit of all, should be developed and extended. In the same way, the consultant and the specialist must be able to go outside hospital at will, either in person or through some other member of their team such as the almoner or social worker. Any attempt to build an administrative wall round the hospital will only result in harm to the practice of medicine.

A most interesting report on "The Quality of Medical Care in a National Health Program" issued in the United States⁹ says that the general practitioner, if given complete consultant reports, "can usually continue with the management of all but the most specialised therapeutic procedures". Some hospital boards and medical societies in the United States have already general practice sections and a "specialty board" in general practice is under discussion. The report advocates the abolition of the closed staffing of hospitals and makes the revolutionary proposal that all licensed practitioners should be allowed to utilise the hospital provided they are restricted to activities within their scope and supervised and aided in their work by the whole professional staff of the institution.

REQUIREMENTS FOR THE FUTURE

Some of the views expressed in this American report are in line with the recommendations of the Cohen Committee on General Practice¹⁰ and other recent British reports, and it is gradually becoming possible to discern the requirements of the future. I suggest that the following points are of fundamental importance.

- 1 The patient of the future will need to be studied in relation to his mental and physical environment. That environment includes home, work, and leisure.
- 2 To do this adequately a number of existing barriers, many of which are artificial and of administrative importance only, must be broken down or ignored.
- 3 The developments of further specialisation in medicine should be discouraged in favour of flexibility.

- 4 The general medical practitioner should be relieved of all non medical burdens and encouraged to develop interests within the hospital and in industrial and preventive medicine.
- 5 There should be no obstacles, administrative or otherwise, to the free access of the hospital team, including the almoner, to the home.
- 6 The general public should be told, preferably by the doctors themselves, that "medical shopping" may of unchecked result in "utility" medicine.
- 7 The maintenance of high standards of medical practice in the future will also require (a) The avoidance of "dilution" or creation of inferior medical posts to replace the more costly expert, and (b) close association between the medical schools, the research worker, the hospitals, and those engaged in domiciliary care.

We are approaching yet another series of crises in the struggle by the medical profession to adapt itself to an unstable environment. When the emotions are let loose it is difficult to take a long view. On the one side are the research departments with ever advancing knowledge of mind and body. On the other is the general public representing what it is now fashionable to call the consumer interest.

Many doctors would also include "they" in this picture—thereby implying those sinister figures whose purpose is supposedly to thwart the free practice of medicine. There is no doubt that an independent and outspoken minority in the community may form an administrative and even a political headache, but it is equally certain that no layman wants to carry the clinician's responsibility. As long as the doctor maintains his skill and dignity so long will he retain his guardianship of the future of the practice of medicine. The moment that he lowers his standards, or allows others to do so for him, medicine ceases to be an art and the disciples of Hippocrates become technicians. The number of people who would wish to see that happen must be very few indeed. Certainly the patients, actual or potential, do not want this.

Fortunately the practice of medicine carries with it incentives which will, in the long run, more than counterbalance the disruptive forces of economic or political necessity and administrative convenience. The joys of craftsmanship remain. Meanwhile there is much to be said for the advice of the Duchess to Alice "Take care of the sense and the sounds will take care of themselves."

EARLY DIAGNOSIS OF SUBACUTE COMBINED DEGENERATION OF THE CORD

VALUE OF GASTRIC BIOPSY

SUBACUTE combined degeneration of the cord, if untreated, progresses inevitably to a crippling conclusion. The march of symptoms may occasionally be extremely rapid. Hence early diagnosis and adequate therapy are essential. However, in Australia at any rate, there are few conditions which so often escape diagnosis until an irrecoverable stage is reached. Delay in diagnosis usually results from (1) failure to recognise the significance of peripheral dysesthesia, which may precede other manifestations by many months, and (2) a reluctance to diagnose subacute combined degeneration of the cord unless

there is a well-defined picture of pernicious anaemia in the peripheral blood. It is the opinion of many observers, and it is also our opinion that subacute combined degeneration of the cord may occur with no significant changes in either the peripheral blood or the bone marrow.

To achieve early recognition of those cases of subacute combined degeneration of the cord where the neurological manifestations are but slight or equivocal, and where the blood changes are minimal or inconclusive, it is necessary, besides detailed neurological examination, to make full use of every additional procedure which may shed light on the diagnosis.

It is the purpose of this study first to emphasise the proper assessment of dysaesthesiae referred to the extremities, secondly to discuss the early changes in the bone marrow in pernicious anaemia, and finally to add a further aid in diagnosis—gastric biopsy. As regards gastric biopsy, it has been our experience that all patients with subacute combined degeneration of the cord and/or pernicious anaemia show considerable atrophy of the mucosa of the body of the stomach associated with histamine fast achlorhydria. The nature of the biopsy fragments thus serves as a valuable guide to the correct diagnosis.

Thus at the outset we may define our attitude towards certain points which have been the subject of controversy—whether subacute combined degeneration of the cord may be associated with the presence of free hydrochloric acid in the gastric contents, and whether any form of anaemia other than the pernicious type may be present.

We believe that the cause is one which tends also to lead to pernicious anaemia and in which histamine fast achlorhydria is constantly present. These are the only cases which we see in Australia. If the term is used in this sense it symbolises a rigid concept. If, however, the term is used in a literal sense, it may include degeneration of the white matter of the cord due to other causes. In these cases free hydrochloric acid may be present in the gastric contents, but only older reports suggested that such cases exist (Grinker 1926). However, we have no personal experience of such cases and believe that they belong to a different group. Secondly, if microcytic anaemia be present, we believe that it is due to other causes commonly leading to anaemia of this type and not directly associated with the disease.

The cases selected are, in the main, those referred to one of us (E. G. R.) for neurological consultation. Cases

with frank pernicious anaemia have not been included for they present no serious diagnostic problem.

EARLY CLINICAL MANIFESTATION

Subacute combined degeneration of the cord presents in various forms. We shall not here describe the pictures which arise from degeneration in the white matter of the cord and in the peripheral nerves. Suffice it to say that sometimes the signs may suggest such diverse conditions as spinal compression and peripheral neuritis.

In advanced cases the diagnosis is usually obvious and confusion is unlikely unless the blood picture is normal or nearly so. Careful inquiry may, however, elicit a history of dysaesthesiae affecting all four limbs at an early stage, before the patient recognised the insidious approach of illness. He complains less of these as time goes on—possibly because they become less obtrusive, possibly because his incapacitating symptoms assume such importance.

The patient with subacute combined degeneration often seeks medical attention during the early stages. Because his complaint is vague and does not indicate the impending gravity of his condition, a diagnosis of neuritis is usually made and he is treated with vitamin B₁. Indeed, these symptoms may be due to degeneration of the peripheral nerves in subacute combined degeneration. The presence of demyelination of peripheral nerves in this disease was demonstrated by Greenfield and Carmichael (1935). The reduction of myelin was of the same type as in alcoholic neuritis. This diagnostic difficulty may be illustrated.

Case 1—A man, aged 63, had noticed that his finger tips became unusually cold during the last two winters. Twelve months ago his fingers had felt numb and puffy and were clumsy. During the last six months his lower limbs had felt stiff. More recently, on rising in the morning, his legs had felt numb from the waist down. When kneeling he had felt as if he was kneeling on bare bone and there had seemed to be tight bands round his knees.

Examination—In spite of the obtrusive nature of the dysaesthesiae, little was found on examination. There was slight ataxia of the lower limbs. Power, tone, and reflexes appeared normal. Vibration was not felt over the knees, ankles or over the sacrum and lumbar spinous processes. This sensation was also diminished over the hands. The threshold for two point discrimination was slightly increased. There was no muscular tenderness. The mucosa of the tongue was slightly atrophic. The cerebrospinal fluid was normal, and a histamine test-meal showed achlorhydria. The peripheral blood and sternal marrow were normal, but the patient had been receiving intermittent liver therapy, which had been instituted without examination of the blood.

Fig 2—Subacute combined degeneration of the cord with no blood changes (case 3). Biopsy specimen of mucosa of body of stomach showing thinning, disappearance of chief and parietal cells and metaplasia to columnar epithelium of intestinal type with plentiful goblet cells. There are no excess wandering cells in supporting stroma. (Stain as in fig 1) ($\times 105$)

are to have beds in hospital, what kind of patient to treat there? Only the doctors themselves can answer these and similar questions, and until they make up their minds they cannot expect the layman to do it for them

The question of access to hospital is a particularly difficult one. The day of the single handed consultant and specialist in hospital is over. He is a member or the head of a team. This is well shown in such a specialty as diagnostic radiology. In one large London teaching hospital the head of the department deals almost entirely in medical work. He has, in his department, one assistant specially trained in neurological work, and another in orthopaedic work. There is also a tendency to specialise within this department in gastro intestinal or chest examinations. It is still more difficult to keep abreast of all recent advances in medicine and surgery and to pass that information to the busy general practitioner. It is clear that the days of Abernethy are over and that the Pooh bah is an anachronism.

It is also true that the practice of medicine cannot follow the artificial administrative divisions of a National Service. The general medical practitioner's work lies mainly outside the hospital, but he must be able to go in and out as he wishes—not in order that he may obtain a "contract" but because he is vitally interested in the patient that he sends in. Alternatively he may possess real ability in some special subject which, for the benefit of all, should be developed and extended. In the same way, the consultant and the specialist must be able to go outside hospital at will, either in person or through some other member of their team such as the almoner or social worker. Any attempt to build an administrative wall round the hospital will only result in harm to the practice of medicine.

A most interesting report on "The Quality of Medical Care in a National Health Program" issued in the United States⁹ says that the general practitioner, if given complete consultant reports, "can usually continue with the management of all but the most specialised therapeutic procedures". Some hospital boards and medical societies in the United States have already general practice sections and a "specialty board" in general practice is under discussion. The report advocates the abolition of the closed staffing of hospitals and makes the revolutionary proposal that all licensed practitioners should be allowed to utilise the hospital provided they are restricted to activities within their scope and supervised and aided in their work by the whole professional staff of the institution.

REQUIREMENTS FOR THE FUTURE

Some of the views expressed in this American report are in line with the recommendations of the Cohen Committee on General Practice¹⁰ and other recent British reports, and it is gradually becoming possible to discern the requirements of the future. I suggest that the following points are of fundamental importance:

- 1 The patient of the future will need to be studied in relation to his mental and physical environment. That environment includes home, work, and leisure.
- 2 To do this adequately a number of existing barriers, many of which are artificial and of administrative importance only, must be broken down or ignored.
- 3 The developments of further specialisation in medicine should be discouraged in favour of flexibility.

⁹ The Quality of Medical Care in a National Health Program. *Amer J publ Hlth*, 1949 39 no 7, July. See *Lancet* Nov 18 1950, p 589.

¹⁰ General Practice and the Training of the General Practitioner. London: British Medical Association, 1950.

- 4 The general medical practitioner should be relieved of all non medical burdens and encouraged to develop interests within the hospital and in industrial and preventive medicine.
- 5 There should be no obstacles, administrative or otherwise, to the free access of the hospital team, including the almoner, to the home.
- 6 The general public should be told, preferably by the doctors themselves, that "medical shopping" may of unchecked result in "utility" medicine.
- 7 The maintenance of high standards of medical practice in the future will also require (a) The avoidance of "dilution" or creation of inferior medical posts to replace the more costly expert, and (b) close association between the medical schools, the research worker, the hospitals, and those engaged in domiciliary care.

We are approaching yet another series of crises in the struggle by the medical profession to adapt itself to an unstable environment. When the emotions are let loose it is difficult to take a long view. On the one side are the research departments with ever advancing knowledge of mind and body. On the other is the general public representing what it is now fashionable to call the consumer interest.

Many doctors would also include "they" in this picture—thereby implying those sinister figures whose purpose is supposedly to thwart the free practice of medicine. There is no doubt that an independent and outspoken minority in the community may form an administrative and even a political headache, but it is equally certain that no layman wants to carry the clinician's responsibility. As long as the doctor maintains his skill and dignity so long will he retain his guardianship of the future of the practice of medicine. The moment that he lowers his standards, or allows others to do so for him, medicine ceases to be an art and the disciples of Hippocrates become technicians. The number of people who would wish to see that happen must be very few indeed. Certainly the patients, actual or potential, do not want this.

Fortunately the practice of medicine carries with it incentives which will, in the long run, more than counterbalance the disruptive forces of economic or political necessity and administrative convenience. The joys of craftsmanship remain. Meanwhile there is much to be said for the advice of the Duchess to Alice: "Take care of the sense and the sounds will take care of themselves."

EARLY DIAGNOSIS OF SUBACUTE COMBINED DEGENERATION OF THE CORD VALUE OF GASTRIC BIOPSY

SUBACUTE combined degeneration of the cord, if untreated, progresses inevitably to a crippling conclusion. The march of symptoms may occasionally be extremely rapid. Hence early diagnosis and adequate therapy are essential. However, in Australia at any rate, there are few conditions which so often escape diagnosis until an irrecoverable stage is reached. Delay in diagnosis usually results from (1) failure to recognise the significance of peripheral dysaesthesiae, which may precede other manifestations by many months, and (2) a reluctance to diagnose subacute combined degeneration of the cord unless

* Aided by a grant from the National Health and Medical Research Council of Australia.

without evidence of either of these two diseases showed lesser degree of thinning of the body mucosa and less trophism of the chief and parietal cells. Intestinal metaplasia was rarely seen, wandering cells including polymorphs were numerous, and there was flattening and sometimes desquamation of the superficial epithelium. We have applied the term "chronic catarrhal gastritis" to this appearance.

Thus the distinction is not absolute but depends on the assessment of changes present in various proportions. Nevertheless we have found biopsy of the stomach mucosa to be a valuable additional aid to diagnosis. It may confirm doubtful cases of subacute combined degeneration, or may exclude chronic alcoholics with peripheral neuritis and with histamine fast achlorhydria due to a catarrhal type of gastritis. Gastritis associated with alcoholic excess usually shows only a mild superficial cellular infiltration with minimal change in the tubular gastric glands but in some cases there may be pronounced catarrhal gastritis with atrophy. Peripheral neuritis and histamine fast achlorhydria associated with chronic alcoholism are illustrated by the following case.

Case 2—A woman, aged 54 was admitted to hospital with five months history of increasing weakness, pins and needles, and cramps in the legs. For the past two months she had been unable to walk without assistance. She had drunk considerable quantities of alcohol during the past year, and

Fig 5—Chronic alcoholism with severe peripheral neuritis (case 2). Biopsy specimen of internal branch of anterior tibial nerve showing gross reduction in number of myelin sheaths. (Osmic acid) ($\times 490$)

her diet had been most inadequate, particularly in first-class protein and vitamins.

Examination revealed mental confusion, general muscular weakness and enlargement of the liver. There were weakness of the lower limbs, tenderness and wasting of the calf muscles, absent deep reflexes and flexor plantar responses. There was some diminution in appreciation of pinprick and vibration in the lower limbs. A histamine test meal showed achlorhydria.

Gastric biopsy revealed superficial gastritis with only minimal atrophy and no intestinal metaplasia (fig 3). It thus differed from the changes seen in the pernicious anaemia-subacute combined degeneration group.

Biopsy of a superficial cutaneous nerve from the foot showed gross reduction in the number of myelin sheaths (figs 4 and 5). This finding has been described by Greenfield and Michael (1935) as occurring both in alcoholic peripheral neuritis and in subacute combined degeneration.

Blood examination showed Hb 13.3 g. per 100 ml., red cells 520,000 per c.mm., and white cells 5200 per c.mm. A smear of peripheral blood was normal.

Liver function tests showed reversal of the albumin-globulin ratio, flocculation of cephalin—but no bile or urobilinogen in the urine.

Liver biopsy showed active hepatitis typical of nutritional disease of the liver (Wood et al. 1949b).

Treatment and Progress.—When the patient was given a high-calorie high-vitamin diet with parenteral vitamin B

Fig 6—Subacute combined degeneration of cord and early pernicious anaemia (case 5). Biopsy specimen of mucosa of body of stomach showing typical atrophy and intestinal metaplasia. (Stain as in fig 1) ($\times 105$)

complex, her mental and physical state improved considerably. However, after three weeks there was still histamine fast achlorhydria, and a second gastric biopsy showed some lessening in the previously observed cellular infiltration of the lamina propria.

This case illustrates the difference between the gastric biopsy findings of a case of alcoholic peripheral neuritis with achlorhydria and cases of pernicious anaemia and subacute combined degeneration.

Case 1 has been presented as a patient in whom difficulty of diagnosis of mild symptoms was resolved by gastric biopsy. In the case now to be outlined we had the misfortune to watch the development of subacute combined degeneration of the cord in the absence of any hematological changes.

Case 3—A male shop assistant, aged 55, was first seen in February, 1948. He had noticed a feeling of numbness under the right costal margin which had appeared about eight years before and lasted two or three years. For the past year his right knee had felt stiff, and he had dragged his leg while walking. There was a feeling of slight stiffness in the left knee. For two years he had had urgency and frequency of micturition without scalding. He had been discharged from the Army as class B in 1918 with "disorderly action of the heart." Seven years previously he had been investigated because of flatulent dyspepsia. He stated that radiography of his gall bladder had been normal and that there had been defective acid in the gastric secretion.

On examination there were no positive neurological findings or local findings in the knee. Investigation gave little further help—the Hb was 14.1 g. per 100 ml. and the blood film normal, but there was histamine fast achlorhydria, with low peptic activity.

The patient was a finicky, introspective man wrapped up in his financial responsibilities to his family and with no outside interests. It was felt that his complaint was functional and with reassurance his urinary symptoms almost completely disappeared. He still had the feeling of stiffness in his knees, but repeated neurological examination showed no abnormal finding.

His symptoms were unaltered twelve months later. However, because of the persistence of the symptoms slight atrophy of the tongue and histamine fast achlorhydria special investigations were again made. The Hb was 15.3 g. per 100 ml. and the mean corpuscular volume within normal limits. The marrow and blood smears were normal. The patient had not received any liver therapy.

Gastric biopsy showed an atrophic mucosa with intestinal metaplasia consistent with the pernicious anaemia-subacute combined degeneration group (fig 2). When the patient was seen by the neurologist (E. G. R.) in consultation, there was evidence of a spastic paraplegia, with some increase in tendon jerks and extensor plantar responses. There was diminution of vibration and position sense in the lower limbs. On admission to the ward some three weeks later these signs had

Fig 3—Chronic alcoholism with severe peripheral neuritis and achlorhydria (case 2). Biopsy specimen of mucosa of body of stomach showing mild surface gastritis with atrophy limited to more superficially placed of darkly staining chief cells and lightly staining parietal cells. There is some excess of wandering cells in upper portion of section (Stain as in fig 1) ($\times 105$)

Gastric biopsy was now done, and the gastric mucosa showed the typical changes of subacute combined degeneration pernicious anemia syndrome. The changes were identical with those illustrated in figs 2 and 6.

Cases simulating peripheral neuritis are usually treated uselessly with vitamin B₁₂ and progress until the diagnosis of subacute combined degeneration becomes obvious. Less often liver is given empirically.

In general it may be stated that the dysaesthesiae are obtrusive and annoying. The degree of discomfort is reflected in the various descriptive similes which the patients use. The dysaesthesiae affect all limbs, if only the lower limbs are affected, some other cause has to be considered. In contrast to the other forms of peripheral neuritis the symptoms tend to outweigh the signs. Indeed for a long period few objective signs may be found. Impairment of appreciation of vibration is the most easily detected sign, but, if this is considerable, there is usually diminution of appreciation of position and passive movement. If the loss is pronounced in the lower limbs, the patient usually does not appreciate vibration over the lumbar spines, and even higher. Loss of superficial sensibility may be difficult to detect, since the patient can detect changes much more effectively than the coarse tests applied clinically. Even when dysaesthesiae have been present for months, motor signs are slight unless the spinal cord is involved. Muscular tenderness is neither so pronounced nor so constantly present as in peripheral neuritis.

EARLY CHANGES IN PERIPHERAL BLOOD AND BONE MARROW

The peripheral blood and the bone marrow may vary from normal to those of frank pernicious anemia. This agrees with the contention of Dacie and White (1949) that there are all grades of deficiency of the essential haemopoietic substance paralleled by corresponding changes in the blood and bone marrow.

It is essential in cases with only minor peripheral blood changes (minor deficiency of haemopoietic substance) to make a comprehensive haematological examination (Wintrobe 1946), including a critical examination of the erythropoietic marrow. The smear of the peripheral blood usually to some degree suggests pernicious anemia, and an increased mean red cell volume and red cell diameter confirm the macrocytic nature of the anemia. Where macrocytosis is present in the peripheral blood, the diagnosis of pernicious anemia is confirmed by finding in the marrow smear some evidence of a

megaloblastic type of erythropoiesis, together with the presence of giant metamyelocytes and hypersegmented neutrophils.

The extent of the megaloblastic change in the marrow is proportional to the quantitative lack of essential factor, thus the appearance may vary from the crowded primitive large megaloblasts containing coarse stippled chromatin with nucleoli, as seen in a gross deficiency, to the form typical of minor grades, where there is a less cellular marrow with only a few smaller and rather mature megaloblasts. Here the major feature of the deviation from normal is an increase of the pale parachromatin at the expense of the basichromatin, giving a nucleus with open lace net pattern. Dacie and White (1944) have termed these forms "intermediate megaloblasts." This is well illustrated in case 5. We have also seen "intermediate megaloblasts" in the marrow smear where a minor degree of deficiency of essential factor has been produced by suboptimal treatment of a case of frank pernicious anemia.

ACHLORHYDRIA AND GASTRIC BIOPSY

In the present investigation gastric biopsy was performed with the flexible gastric biopsy tube designed in this unit (Wood et al 1949a). By this method fragments of mucosa 1 mm in diameter and extending down to the muscularis mucosae (fig 1) can be obtained with minimum discomfort to the patient. Even in seriously ill patients gastric biopsy can be carried out with little upset.

We consider that histamine fast achlorhydria is a constant finding in subacute combined degeneration of the cord, and gastric biopsy in our cases has shown corresponding atrophic changes in the mucosa of the body of the stomach. The appearance of the gastric mucosa is reasonably constant. There is always thinning, with atrophy of the pepsin secreting chief cells and the acid secreting parietal cells. This atrophy may be complete or a few scattered remnants may survive. Metaplasia of the epithelium to an intestinal type with plentiful mucus goblet cells is often extensive. The stroma may show some wandering cells of mononuclear type, but polymorphs are always absent or scanty (fig 2).

The histological appearance of the gastric mucosa in this pernicious anemia, subacute combined degeneration group is not entirely specific, but in biopsies from 278 patients chiefly suffering from dyspepsia we have seen only 2 cases with extreme atrophy, thinning, and intestinal metaplasia who have not already had, or subsequently developed, the signs of pernicious anemia and/or subacute combined degeneration of the cord. There were 26 cases of established pernicious anemia in this group. All the other cases having histamine fast achlorhydria.

Fig 4—Biopsy specimen of internal branch of anterior tibial nerve from healthy person showing normal number of darkly staining myelin sheaths (Osmic acid) ($\times 490$)

are present over pressure points. Retention of urine with overflow had led to severe cystitis. There was irregular enlargement of the uterus, and on admission carcinoma of the uterus with spinal metastases had been tentatively diagnosed. Lumbar puncture revealed a normal c.s.f. Radiography of the lumbar spine was normal. Subacute combined degeneration was suspected, and confirmatory evidence was sought.

Blood examination showed Hb 8.8 g per 100 ml, red cells 820,000 per c.mm., and packed erythrocyte volume of 31%. The film showed a moderate degree of anisocytosis and oikocytosis, but macrocytes were not obvious. There was neutrophil leucocytosis. Calculation of the mean red cell values gave a volume of 117 c. μ and a Hb content of 33 μ g.

Bone marrow—The significance of the very considerable increase in mean red-cell volume was confirmed by the sternal marrow smear, which showed a cellular marrow with a relative increase in erythroid elements, a small proportion (2%) of which were "intermediate megaloblasts" (fig. 7). Giant metamyelocytes numbered about 3% of the nucleated cells present. There was a histamine fast achlorhydria.

Gastric biopsy showed a greatly thinned mucosa with complete atrophy of chief and parietal cells (fig. 6). There was complete metaplasia of the epithelium to intestinal type.

Treatment—Injections of liver extract were started, but response was unsatisfactory. The urinary sepsis proved difficult to control, and the patient died six weeks after admission.

Necropsy Findings—There were gross atrophy of the mucosa of the body of the stomach and typical degeneration of the posterior and lateral columns of the cord, with absence of gliosis (fig. 8).

This case illustrates the necessity for volumetric red-cell determinations, since without this the macrocytosis was not obvious. The recognition of "intermediate megaloblasts" and giant metamyelocytes in the marrow smear, and the finding of an atrophic gastric mucosa by biopsy, clinched the diagnosis of subacute combined degeneration. An incomplete haematological examination made several days before the patient's admission to hospital had not provided the correct diagnosis.

DISCUSSION AND SUMMARY

In pernicious anaemia the bone marrow, blood, and gastric mucosa show characteristic changes. These are respectively megaloblastic hyperplasia, macrocytosis, and atrophy. In subacute combined degeneration of the cord the changes in the haemopoietic system are sometimes not obvious. In these cases the diagnosis may be confirmed by the finding of intermediate megaloblasts in the bone marrow and increase in the mean erythrocyte volume and diameter. Biggs and Macmillan (1948) have shown the colour index to be a misleading guide in diagnosis. They predict a return to Price Jones curves.

Sometimes, however, the results of all these examinations are normal. If there is free hydrochloric acid in a test-meal, the diagnosis of subacute combined degeneration is, we believe, untenable. If there is histamine fast achlorhydria, the correct diagnosis may be, and probably is, subacute combined degeneration. However, a few conditions—e.g., alcoholic peripheral neuritis—may be associated with histamine fast achlorhydria. Thus, this test lacks certainty. Gastric biopsy will serve to separate such cases of peripheral neuritis. The biopsy is of greater value in diagnosis than is a test meal alone. It will allow of an almost certain diagnosis at a stage in which the patient complains only of dysesthesiae with normal haematological findings. Gastric biopsy may indicate the diagnosis of subacute combined degeneration in cases with advanced neurological signs where the diagnosis is uncertain on clinical grounds.

Lastly, at any stage it may help in solving the recurrent problem of diagnosis after injudicious liver therapy.

In practice, however, early diagnosis depends on the appreciation of the importance of mild neurological

symptoms. If paraesthesiae, with or without neurological signs, suggest the diagnosis, it is essential to give a test meal and to examine the blood for macrocytosis and the bone marrow for megaloblasts. If doubt still exists, gastric biopsy provides a criterion for recognition or exclusion of subacute combined degeneration of the cord.

We wish to thank members of the honorary medical staff of the Royal Melbourne Hospital who have referred cases to us. The photomicrographs were prepared by Mr E. Matthaei, of the University of Melbourne.

THE association of diabetes and pregnancy was a medical curiosity before the introduction of insulin, since then, however, pregnancy in the diabetic has become increasingly frequent, and it has long been recognised that it leads to a very high foetal mortality which is apparently little affected by careful control of the maternal diabetes. Foetal gigantism is a further feature of this association. A striking result of recent investigations has been the demonstration that these foetal effects are found before the onset of diabetes in the pregnancies of women who subsequently develop diabetes (prediabetic pregnancies) (Miller et al. 1944, Miller 1945, Henley 1947, Barnes and Morgans 1948, Gilbert and Dunlop 1949, Gilbert 1949). That the prediabetic phase may be a long one is shown by the finding of Barnes and Morgans (1948) that the total late foetal mortality-rate, consisting of intra uterine deaths, stillbirths, and neonatal deaths but excluding abortions, begins to exceed that for normal pregnancies about fifteen years before the onset of diabetes.

It seems reasonable to suppose that the most important factors responsible for the effects on the foetus in prediabetic and diabetic pregnancies are similar if not identical, and it was suggested by Barnes and Morgans (1948) that the large infant of the prediabetic and diabetic mother and the subsequent development of diabetes in the prediabetic woman might be due to an overproduction of the "diabetogenic-growth complex".

become even more obvious. Because the signs and symptoms were confined to the lower part of the body, it was considered wise to exclude spinal compression. Queckenstedt's test, examination of the cerebrospinal fluid (CSF), and opaque myelography were normal.

Treatment—The patient was started on a course of 'Cam polon'. A maintenance course of 10 ml every two weeks did not check mild deterioration in subjective findings. The liver treatment was continued for five months, but interrupted when the patient attended an osteopath. At the end of a further three months it was found that his plantar responses were much less definitely abnormal than before. He complained, however, of deterioration of his condition and stated that he had some dysaesthesiae in the hands. Admission to the ward was arranged for treatment with vitamin B₁₂. When examined shortly after the first injection his plantar responses were flexor. Gastric biopsy was repeated at the second admission and showed the initial picture. Histamine test-meals have persistently shown achlorhydria with low peptic activity.

In this patient objective neurological signs did not manifest themselves even two years after the onset of symptoms. Shortly after a typical gastric biopsy picture had been obtained, signs of paraplegia were obvious. Had biopsy been done earlier we feel that, despite atypical symptoms with no signs and no anaemia, a correct diagnosis would have been made and earlier treatment instituted.

A second and similar problem is presented when there has been a haphazard use of liver extract for the treatment of incompletely investigated anaemias. This malpractice is undoubtedly world wide. It may lead to suboptimal treatment of a suspected case of pernicious anaemia which has not been positively identified either before or after liver treatment was begun. In such a case nervous changes suggesting subacute combined degeneration of the cord may develop in spite of a nearly normal blood picture. The physician is then confronted with the problem of both diagnosis and treatment. Should he assume the diagnosis of pernicious anaemia, subacute combined degeneration syndrome and commit the patient to a lifelong course of liver injections? Or should he cease treatment for a time to watch for the appearance of undoubted pernicious anaemia or subacute combined degeneration? This latter course would be fraught with much danger if the diagnosis is subacute combined degeneration, for the march of nervous symptoms may be rapid and, although liver injections may halt this progress and cause some improvement, irreparable damage may have been done. Here gastric biopsy is of great value, for, should the gastric mucosa show the stigmata of severe gastric atrophy, this would support the diagnosis of subacute combined degeneration of the cord. This is illustrated by the following case.

Case 4—A woman, aged 57, had five years' history of gradually increasing weakness in the legs. For the last two

years she had been unable to walk, and there was loss of sphincteric control. A year ago her physician had first suspected pernicious anaemia and subacute combined degeneration and prescribed liver tablets. A satisfactory blood examination had not been made. The patient had continued to take the liver tablets in suboptimal amounts but she had ceased to obtain medical attention. On her admission to hospital a spinal tumour was provisionally diagnosed.

Examination showed general wasting and weakness, diminished deep reflexes, extensor plantar responses, and gross impairment of posterior-column conduction. There was loss of sphincteric control, with severe infection of the bladder and a large sacral bedsore. Lumbar puncture was normal. The Wassermann reaction in blood and CSF was negative. A histamine test-meal showed achlorhydria. Blood examination showed Hb 8.4 g per 100 ml, red cells 3,040,000 per c mm, leucocytes 20,000 per c mm, and anisocytosis and occasional poikilocytes in a blood film. Volumetric estimations were not made. A bone marrow smear showed increased normoblastic erythropoiesis. Serum bilirubin 4 units. The patient now came under our observation.

Gastric biopsy revealed gross atrophy of the mucosa of the body of the stomach, typical of pernicious anaemia.

Treatment—With liver injections and control of urinary infection there was improvement in the anaemia, the Hb rising from 8.4 to 13.3 g per 100 ml in six weeks. There was only slight improvement in the nervous signs.

This elderly woman developed paralysis in the legs and loss of sphincteric control. Pernicious anaemia and subacute combined degeneration were suspected by her medical attendant, but an adequate blood examination was not made at that time. Oral liver therapy was ordered but was continued in suboptimal dosage without medical control. After admission to hospital pernicious anaemia was suspected, but a confident diagnosis was not made. The blood and marrow appearances had been rendered inconclusive by the prior administration of oral liver. Gastric biopsy provided strong supporting evidence of subacute combined degeneration.

The difficulties experienced in reaching a clinical diagnosis of subacute combined degeneration and the value of the various tests are well illustrated in the following case.

Case 5—A woman, aged 64, had developed retention of urine and increasing weakness of both legs two weeks before admission to hospital. She could walk only a few steps. Previous to this her health had been good.

On examination she was found to have a smooth atrophic tongue and wasting of her leg muscles, with gross weakness of all movements. Knee and ankle jerks were absent, plantar responses were extensor, and sensation to light touch and pinprick was absent over both legs and thighs. Perception of vibration was absent at the right knee and ankle. Bidsore

Fig 8—Lumbar portion of spinal cord showing extensive degeneration of posterior and lateral columns with absence of glial reaction (case 5) (Weigert.)

was 153, there were 27 stillbirths (18%), and of the live born rats 24 (19%) died within forty eight hours (table I). Only 50% of the live born rats were weaned. Foetal resorption occurred in 3 instances, as indicated by uterine bleeding after an initial rise in body weight, followed by a fall in weight to the preconception levels. More detailed descriptions of the course of diabetes and pregnancy in the alloxan diabetic rat will be published elsewhere.

Controls and Crude A.P.E

There were 30 pregnancies in the control group, producing 218 young, of which 6 (2.75%) were stillborn, of the live born rats 4 died within the first forty eight hours, the neonatal mortality thus being 1.9%. (Since no differences were observed between the controls injected with saline solution and those injected with liver extract, they have been grouped together.)

The dosages of A.P.E. used and the incidence of stillbirths and neonatal deaths are shown in table I. It can be seen that, when the dose reached 0.25 ml a day, the stillbirth rate was practically 100%. Many of the stillborn foetuses were macerated or partly eaten, and in some cases the maternal loss of weight on delivery was so discrepant from the number of foetuses found that one had to conclude that some had been eaten completely, because of this the sign > has been used in table I where uncertainty existed, and in calculating the stillbirth rates it has been assumed that only stillborn foetuses were eaten.

TABLE II—COMPARISON OF GONADOTROPIC ACTIVITY OF C.G. AND FRACTIONATED A.P.E. IN 22 DAY OLD FEMALE RATS

Groups	No of animals per group	Group means and standard deviations	
		Weight of ovaries (mg)	Weight of uterus (mg)
Controls	10	12.1 ± 2.9	29.0 ± 8.1
C.G. 10 I.U. a day	9	24.4 ± 3.7	97.7 ± 18.3
C.G. 40 I.U. a day	10	29.4 ± 7.3	116.6 ± 16.4
Fractionated A.P.E. 0.25 ml. a day	10	10.9 ± 1.6	27.5 ± 5.1
Fractionated A.P.E. 2.0 ml. a day	10	12.2 ± 1.8	25.6 ± 4.7

Chorionic Gonadotrophin

It is possible that crude A.P.E. (ox) may contain the luteinising factor in considerable quantity (cf Young 1939), and, since the effects of the extract might have been due to this hormone rather than to the diabetogenic growth complex or other factors, it was thought justifiable to test the effects of chorionic gonadotrophin (C.G.), which was the most readily available source of gonadotrophin with an almost purely luteinising action. The effects of various doses of C.G. are shown in table I, from which it can be seen that the stillbirth rate was at least 8% with a dose of 12.5 I.U. a day, but that with higher doses all the foetuses died in utero and the mothers remained undelivered, either the foetuses being completely resorbed or the mothers dying. Non delivery of the mother after intra uterine death of the foetus was also found in some of the rats on the higher doses of crude A.P.E.

Fractionated A.P.E

It will be seen that the effect of C.G. on foetal mortality resembles that of crude A.P.E. Possibly, therefore, the lethal action of the crude A.P.E. could have been due to its assumed content of luteinising factor, and it was therefore of considerable interest to see whether an A.P.E. fraction believed to be free from gonadotrophin but known to still contain the diabetogenic growth complex would have similar effects on the foetus. Tests for gonadotrophic activity were made on two batches of

Crude A.P.E. 0.1 ml a day	4	2.25 ± 1.3	9.75 ± 2.2
Fractionated A.P.E. 0.1 ml a day	5	2.8 ± 0.45	8.8 ± 1.6
Fractionated A.P.E. 0.2 ml. a day	4	2.75 ± 0.5	9.75 ± 0.9

fractionated A.P.E. by three different methods. In the first of these the test animals were 22-day old female rats weighing 26–42 g. These were divided into five groups, of which one (controls) received injections of saline solution 0.5 ml, two received C.G. 10 I.U. and 40 I.U., and two received the fractionated A.P.E. 0.25 ml and 2 ml, the volume of which had been adjusted so that the diabetogenic potency was about equal to that of the crude A.P.E. Subcutaneous injections were given daily for three days, and the rats were killed with ether on the fifth day. The ovaries and uteri were dissected out and weighed. The results are shown in table II, from which it can be seen that the test animal was a sensitive preparation for C.G. and that the fractionated A.P.E. had no detectable gonadotrophic activity.

In the second test a comparison was made between the gonadotrophic activity of the crude and fractionated A.P.E. in 21 day-old female mice weighing 10–17 g. These were divided into five groups, of which one (controls) received injections of saline solution 0.2 ml, two received crude A.P.E. 0.05 ml and 0.1 ml, and two received fractionated A.P.E. 0.1 ml and 0.2 ml. The mice were treated in the same way as the rats, and the results are shown in table III, from which it can be seen that the doses of A.P.E. used had no detectable gonadotrophic activity.

Because there are theoretical objections to these methods of detecting luteinising hormone, it was thought advisable to make a further test, using the rat prostate and seminal vesicle as the indicator preparation. Loraine (1949) has shown that the weight of the rat prostate is a convenient index for the assay of chorionic gonadotrophin. Of five groups of 21 day old male rats weighing 32–50 g. one (controls) received injections of saline solution 0.4 ml, two received C.G. 0.66 I.U. and 1.33 I.U., one received crude A.P.E. 0.25 ml, and one received fractionated A.P.E. 0.5 ml. Injections were given as described above, and the rats were killed on the fifth day, when the prostates and seminal vesicles were removed and fixed in formal saline. Subsequently they were dissected free from surrounding tissues and weighed. The results are shown in table IV, from which it must be concluded that

TABLE IV—COMPARISON OF GONADOTROPIC ACTIVITY OF C.G., FRACTIONATED A.P.E., AND CRUDE A.P.E. IN 21 DAY OLD MALE RATS

Groups	No of animals per group	Group means and standard deviations	
		Weight of prostate (mg)	Weight of seminal vesicles (mg)
Controls	6	49.7 ± 8.5	7.5 ± 2.0
C.G. 0.66 I.U. a day	5	50.0 ± 8.5	11.9 ± 1.4
C.G. 1.33 I.U. a day	5	84.4 ± 27.9	18.8 ± 4.4
Crude A.P.E. 0.25 ml a day	5	50.0 ± 12.3	6.0 ± 1.2
Fractionated A.P.E. 0.5 ml a day	5	57.6 ± 18.6	9.4 ± 3.5

by the maternal anterior pituitary gland, the overactivity of which might in addition be responsible for the high late foetal mortality rate in the pregnancies in question. A similar suggestion about the foetal gigantism has been made by Gilbert (1949).

The present investigation is an attempt to see whether experimental support for this hypothesis can be provided by studying the effects on the foetal mortality rate in pregnant rats of treatment with anterior pituitary extracts (A.P.E.) containing the diabetogenic growth complex. The rat, while receiving these injections, might reasonably be considered as in the "prediabetic state," although it is impossible to induce diabetes, or even hyperglycaemia, in the rat by repeated injections of this extract (Young 1938), the reaction of the rat resembles that of puppies injected with the extract in so far as increase of growth rate is the principal effect observed (Young 1941). Because there have been conflicting reports of the effect on foetal mortality of alloxan diabetes—e.g., Davis et al. (1947) and Miller (1947)—it was thought wise to reinvestigate this point, so as to compare the effect of hyperglycaemia, primarily of pancreatic origin, with that of A.P.E.

EXPERIMENTAL

Virgin adult female rats were used for the experiments recorded here. Alloxan diabetes was induced in two strains of albino Wistar rats weighing 170–230 g by a subcutaneous injection of 20 mg of alloxan per 100 g of body weight on each of two successive days (Dunn and McLetchie 1943), one group was starved for forty-eight hours before the first injection and fourteen hours between injections to increase susceptibility to alloxan (Kass and Waisbren 1945). When the diabetes had become established, the rats were put with bucks and were segregated just before delivery. Repeated pregnancies took place in some of these rats. The diabetes was not controlled with insulin.

The rats used for A.P.E. injections were virgin females, weighing 120–200 g, of mixed strains. Only one pregnancy per rat was permitted in this series. They were put with bucks, and daily vaginal smears were examined. At first the finding of a vaginal plug was taken as an indication of conception, but it was found to be unreliable as evidence of conception. Its use was therefore abandoned, and instead the so-called "placental sign" (vaginal bleeding at about the fourteenth day of pregnancy) was adopted as the indication of conception. Even this was sometimes unreliable. Subcutaneous injections were started on the day of finding the placental sign and were given daily until delivery or death of the rat. In each series of experiments control animals were injected daily with 0.25 ml of physiological saline solution or of an alkaline saline extract of acetone dried liver prepared in the same way as A.P.E. and used to exclude the possibility of non-specific protein effects.

The "crude A.P.E." used initially consisted of a Seitz filtered extract containing 0.01% 'Merthiolate' (Eli Lilly & Co.). It was prepared from fresh ox anterior pituitary glands, by extraction with alkaline saline, essentially according to the procedure described by Young (1939, 1941). The extract contained all the hormones present in ox anterior pituitary tissue, which is, however, a poor source of follicle stimulating hormone and of adrenocorticotrophic hormone. Of this extract 1 ml (equivalent to 0.25 g of anterior lobe tissue) contained 15–20 mg of protein, of which 3–5 mg was growth hormone—an amount sufficient to produce striking growth in the non-pregnant adult female rat when injected over the course of a fortnight. Although purified growth hormone is diabetogenic (in the cat) per se (Cotes et al. 1949a), the possibility cannot be excluded that the "diabetogenic growth complex" involves not only growth hormone (cf. Cotes et al. 1949b) but also traces of other factors, such as adrenocorticotrophic hormone.

The "fractionated A.P.E." used in certain experiments was a "saline supernatant" fraction prepared by electro-precipitation from crude A.P.E. (Reid and Young 1948, Reid 1949). About two thirds of the protein in such a fraction consists of growth hormone, and it is again possible that traces of, say, adrenocorticotrophic hormone present in the fraction are a constituent of the "diabetogenic growth complex". The method of preparation was such that the fraction was unlikely to contain gonadotrophins in appreciable amounts.

The chorionic gonadotrophin was a standardised preparation from human pregnancy urine containing 100 i.u. per mg. Its solution in distilled water was freshly prepared before each injection.

All the rats were weighed daily either throughout pregnancy or from the time of appearance of the placental sign. They were kept at 72°F and were fed a vitamin enriched cube diet ad lib. At the end of the pregnancy the numbers of live births and stillbirths were noted, the live young being returned to their mothers and observed during the succeeding days for neonatal and infant deaths. Summary data of the rats are shown in table 1.

RESULTS

Alloxan Diabetes

Of 47 animals injected with alloxan 23 died in the first few days, 4 were not affected, and 20 developed permanent severe hyperglycaemia (blood sugar levels 220–700 mg per 100 ml), glycosuria, polydipsia, and polyuria. Ketosis was not detected during twelve months' observation, but nevertheless all the animals developed cataracts two or three months after injection. A total of 27 pregnancies occurred in 14 of these diabetic rats over an average mating period of about 300 days. The total number of young born from 24 pregnancies

RENAL-TRACT DELAY TIME AND DEAD SPACE

R R MCSWINEY

DURING investigations into renal function it became necessary for us to know the time elapsing between the formation of urine in the kidney and its appearance from the end of a urethral catheter. After urine has been formed it must traverse the renal collecting tubules, calyces, and pelvis, the ureter, the bladder, and the urethral catheter, the volume of all these structures together is here referred to as the "renal tract dead space" and the time needed for the urine to traverse them may be called "renal tract delay time".

Smith et al (1938) estimated that the renal tract delay time averages 150 sec at urine flows of 2-6 ml a minute, but Goldring and Chasis (1944) say "there is a large dead space in the collecting tubules, pelvis, and ureters, and the appearance time of the dye will vary inversely with the rate of urine flow". There seems to be a discrepancy between these two statements. We have not found any other published observations on delay time and dead space, although there are several speculative statements in the published work—for instance, Brun et al (1945) remark that "the size of the dead space is difficult to judge but it may be estimated at about 5-10 ml". Finally, though Schwartz et al (1949) recognised that renal dead space might involve errors in the determination of extracellular fluid volume by their method and noted that their "data are not corrected for renal dead space," they gave no method for estimating it.

Our observations depend on the principle that if the dead space is x ml and the urine flows at v ml a minute, the delay time is x/v . Since urine flow is easily measured, if either the delay time or the dead space is known the other can be calculated.

TECHNIQUE

Twenty four observations were made on 17 persons with regular urine flows of 0.6-14.0 ml a minute. A multi-eyed urethral catheter (internal volume 2 ml) was passed, and the spontaneous flow of urine from the end of the catheter

was measured for several minutes. Then 0.6 g of sodium aminohippurate (P.A.H.) in 20 ml of isotonic saline was rapidly injected into an antecubital vein, and a stop watch was started. At the same instant urine collections were begun, and when sufficient urine had been collected the urine flow was again measured.

The volume of each urine collection was next measured to ± 0.1 ml and reagents of Bratton and Marshall (1939) were added to each separate collection, these reagents gave an intense reddish purple colour with very small quantities of P.A.H., so that the presence of this injected substance could readily be detected in the urine.

It was regularly found that P.A.H. was absent from several collections after the intravenous injection, a trace would then appear, and in subsequent collections the concentrations would increase and soon reach a maximum. This absence of a clear end point showed, as expected, that considerable mixing took place in the dead space and made an accurate estimation of its volume impossible. Nevertheless, the dead space could not be smaller than the volume of the collections made up to the detection of the trace of P.A.H. (minimal dead space), nor larger than the volume of the collections made when the maximal concentration first appeared (maximal dead space). In the earlier experiments these collections were made, irrespective of time, in volumes of about 1 ml, and, within rather wide limits, the dead space could be measured, from a measure of the urine flow the delay time was then calculated. In later experiments urine collections were made in timed periods of 10 sec, irrespective of volume, and the delay time and dead space could both be directly measured with the same limitations.

To 3 persons, when P.A.H. delay time and dead space had been estimated at comparatively low rates of urine flow, water was given in large amounts. About an hour later, when a high stable urine flow was reached, the dead space and delay time were determined again after a fresh injection of P.A.H. The P.A.H. originally injected had nearly disappeared from the urine, and the end point of this second experiment could be detected with the same ease (and limitations) as before.

In 6 persons the delay time was measured after a intravenous injection of methylene blue (100 mg in 1 ml) by timing its first appearance in the urine, 2 of these had had a previous determination made with P.A.H. an hour or so before at a different rate of urine flow.

Clearly this method of estimating delay time and dead space can only be applied if the urine flow is almost continuous and regular. The flow of urine from a catheter is often intermittent, with spontaneous cyclic interruptions. We have rejected seven observations in people in whom the interruption has lasted longer than 20 sec.

Fig. 1—Relation of dead space to urine flow; circles denote P.A.H. average dead space of each experiment shown in the accompanying table, squares denote methylene blue dead space.

no gonadotrophic activity could be detected in either A.P.E. preparation

Injections of a batch of fractionated A.P.E. 0.5 ml daily, equivalent in diabetogenic potency to about 0.4 ml of crude A.P.E., were given to pregnant rats (table 1). Altogether 35 foetuses were counted, of which 29 (83%) were stillborn. (There were probably some completely eaten foetuses in addition.) With two subsequent batches of fractionated A.P.E., injected in amounts equivalent in diabetogenic potency to 0.25 ml of crude A.P.E. daily, somewhat different results were obtained. Several rats delivered litters which were either alive or at most contained one or two stillbirths. The remainder showed vaginal bleeding due to placental separation, with intra uterine death of foetuses, and died undelivered. The foetal mortality in these two groups was 29 out of 37 (88%), and 34 out of 66 (52%).

DISCUSSION

From the foregoing results it seems possible to draw certain clear conclusions. First, pregnant alloxan-diabetic rats produce an increased number of stillbirths (18% compared with 4% for controls), but pregnant rats treated with relatively high doses of crude A.P.E. produce 100% of stillbirths. The results of injections of C.G. suggested that at least some of this mortality could be due to the assumed content of luteinising factor in the crude A.P.E. preparation. An attempt was made to ascertain whether the crude A.P.E. did, in fact, have gonadotrophic activity. Administration of crude A.P.E. to immature female mice or male rats did not significantly influence the weights of the ovaries and uterus or of the prostate and seminal vesicles respectively, although C.G. was highly effective in the male rats and is well known to be similarly effective in immature female mice. On the other hand, extracts from ox pituitaries, in contrast to those from sheep or hog pituitaries or to non-pituitary gonadotrophins, may be highly effective in inducing ovulation in the rabbit, but almost ineffective in influencing the weight of the ovaries or of the seminal vesicles of immature rats (Wallen Lawrence and Van Dyke 1931, Chance et al 1939, Noble et al 1939). A further complication in the case of the rat is the occurrence of strain differences, as demonstrated by Fraenkel Conrat et al (1940) a strain which was sensitive to urinary or serum gonadotrophins was insensitive to a sheep pituitary preparation, and the converse was found with another strain.

Fractionated A.P.E. preparations, which were anticipated to be essentially free from gonadotrophins, did not show gonadotrophic activity in the tests, but this result should be interpreted with caution in view of the failure to show activity with crude A.P.E. However, since the fractions consist predominantly of growth hormone, and produced a lethal effect on the foetus in some instances, it seems likely that growth hormone, or at least the "diabetogenic growth complex," is the important factor in producing this effect. The variability in the effects on foetal mortality of different batches of fractionated A.P.E., although difficult to explain, is in conformity with the results obtained by Watts (1935).

The high mortality of live born young of alloxan diabetic rats deserves comment. It could be due to the abnormal intra uterine environment, to defective lactation, or to both, and, since the distribution of deaths in the alloxan diabetic and A.P.E.-injected rats is so different, one is inclined to regard defective lactation as an important element contributing to the deaths of 50% of the live born young of alloxan diabetic rats.

It is felt that the evidence presented here is consistent with the suggestion of Barnes and Morgans (1948) about the lethal factor in prediabetic and diabetic pregnancies, it makes no contribution towards a solution of the problem of the overweight baby characteristic of these

pregnancies, for which purpose the arrangement of the experiment was unsuitable.

SUMMARY

A comparison has been made of the foetal mortality of rats made diabetic with alloxan and that of pregnant rats given injections of ox anterior pituitary extracts (A.P.E.) containing the "diabetogenic-growth complex." For the former the stillbirth rate and neonatal death rate were 18% and 19% respectively, though of the live-born young only 50% were weaned. With suitable doses of crude A.P.E., however, 100% of stillbirths were obtained.

Because the crude A.P.E. might have contained appreciable amounts of the luteinising factor, the effects of chorionic gonadotrophin were investigated. It was found that suitable doses caused intra uterine death with failure of delivery of the uterine contents, followed either by resorption or maternal death.

A fractionated A.P.E., still containing the "diabetogenic growth complex" but believed to be gonadotrophin free, was given to pregnant rats. Different batches produced variable results, the foetal mortality being 52-88%.

It is felt that these results are consistent with the hypothesis that overproduction of the "diabetogenic growth complex" by the maternal anterior pituitary may be responsible for the high late foetal mortality rate in prediabetic and diabetic women as well as for the subsequent development of diabetes in the former.

The cost of the pituitary glands used in this investigation was defrayed by a grant from the Medical Research Council to Prof. F. G. Young. We are indebted to him for making the crude A.P.E. available, for this and for his interest and advice, as well as for that given by Prof. H. P. Himsworth. We wish to express our sincere thanks.

"The man in the street, or more correctly, the woman in the home has to cope with a more varied selection of social visitors than is necessary the harassed housewife might well be forgiven if she suggested that many of their functions might well be entrusted to one 'general purposes' visitor to whom she could tell all her social problems, and who would be interested in all her children, and in all her difficulties. The remedy would appear to be that the health work of the hospital should be carried out by the health visitors of the local authority. This suggestion is not administratively tidy, and would call for much day-to-day improvisation. But it is better to have continuous crises in the administrative machine than to have them amongst the public which it serves."—Dr HUGH PAUL, M.O.H. for Smethwick, in his report for 1949.

he skin, containing serosanguineous or seropurulent fluid. About thirty crusts marked the sites of less recent bullæ. Some were yellow at first and to all appearances like those of ecthyma. Others were dense, dry, adherent, and black, these did not fluoresce in Wood's light, and their colour was attributed to altered blood.

On shedding of the crusts, several types of residual scar could be recognised. There were depressed scars, paler than the normal skin, with a tissue paper type of epidermal atrophy and hyperpigmented scars with partial loss of hair. Larger and deeper scars showed white epilated centres surrounded by a hyperpigmented partially epilated zone which merged peripherally with normal skin and hair. There were also varioliform pits, some normally and others excessively pigmented, and scars of pinhead size, seen mostly on the back of the neck. The two largest scars were on the scalp; they were each 4 cm across and were hairless. Numerous smaller (2 cm) scars scattered over the scalp showed varying degrees of cicatricial alopecia. The forehead along the hair margin had been severely scarred and on the face itself the nose and circumoral area were worst affected. Here a number of varioliform pits were present. Numerous flat slightly depressed scars, 1-2 cm across, were evident on the extensor aspects of the forearms and dorsa of the hands and a similar state was found on the thighs, legs and dorsa of the feet. On the upper thighs only a few dark varioliform pits were present. On the palms there was a stippled obliteration of the papillary ridges in places where there had been small lesions. In two scars on the legs symmetrically placed near the heads of the fibulae, the atrophic epidermis was ballooned out by a firm, slightly tender underlying growth suggesting keloid formation; there was no keloid elsewhere.

One of these swollen scars was partially excised with a portion of the adjoining skin. In Wood's light this piece of tissue showed no fluorescence. After examining it histologically Dr J F Murray reported: 'That fragment which lay in the normal area shows slight subepithelial oedema of the corium and dilation of the capillary vessels. There is very slight perivascular round-cell infiltration in the upper corium. The collagen bands are loose and broad in this area and there is a marked increase in number and calibre of the elastic fibres which are markedly fragmented. The fragment of skin which lay in the tumour shows closely packed narrow bundles of collagen resembling scar tissue. In this area elastic tissue fibres are almost completely absent and those which exist are small and narrow. The scar tissue extends up to the basal layer. In both areas the pigmentation of the basal layer is well marked but does not appear to be increased and no aberrant pigment has been found. There is no evidence of keloid or of neoplasia.'

A few small deep seated purpuric spots were noted on the dorsal aspect of the hands and fingers. In this region there were also many epithelial elevations, each about the size of a grape seed situated around but not over the prominences of the knuckles and in the dorsal aspect of the interdigital webs. These were taken to be milia.

All the exposed parts showed slight hyperpigmentation, coarseness and inelasticity of the skin these features being most evident on the back of the neck. The skin generally was dry and powdery, sweating was not observed. The child wore a short sleeveless dress, and—in contrast to the unprotected areas—the skin covered by this garment was free from signs of present or past involvement. The nature and distribution of the primary lesions and their residual scars established the diagnosis of *hydra aestivale*.

Fingers and Toes—The fingers were claw like and restricted in range of movement at all joints; the hand could neither be placed flat nor clenched. The palms were moderately hyperkeratotic and stiff. The skin around the digits was tightly drawn, creating a spurious impression of a fusiform thickening around the joints. The pulp of the terminal phalanges was sclerotic translucent, retracted and devoid of papillary ridges. The child was right-handed and these changes were especially noteworthy in the thumb, index, and 5th fingers of that hand. Following this atrophy the paronychia tissue had been drawn away as it were from the sides of the nails, leaving them projecting well over the finger tips. On the radiographic appearances Dr C Komins reported: 'There is erosion of the terminal phalanges of the thumb, 2nd and 3rd fingers and possibly the 5th as well. Nicks into the tufts of the terminal phalanges of both ring fingers are evident. Further, the phalanges of the 1st and

2nd fingers show early development of the so-called stub deformity. The soft tissues of the fingers show corresponding changes. An unusual feature is that there appears to be an accessory epiphysis in the middle and ring fingers.'

All the nails of the hands showed dystrophic changes, a spontaneous detachment had occasionally occurred. The nail plates were ridged longitudinally and transversely, being 2-6 mm in thickness at their free edges. The right thumb nail was beak like. In Wood's light the nails appeared dull.

The toes were splayed, slender and tapered. There was no atrophy or sclerosis comparable with that seen on the fingers. One great toenail had been shed and the other toenails showed varying transverse lamination and development of spoon shape. The soles of the feet were supple and showed no thickening or scarring.

The Hair—The scalp hair was of normal growth and extent except in the upper forehead where the hairline had receded irregularly because of numerous scars. The eyebrows were thin and separate from one another; a few longer and more curly hairs in their outer thirds gave them a slightly bushy appearance. Eyelashes were normal. There was a small growth of curly hair in the apex of each axilla; pubic hair was absent. On the sides of the cheeks, in an area roughly coincident with that occupied by the side whiskers in an adult male, there was a thick growth of fine silky hair and only slightly curly hair. Above it was contiguous with the scalp hair just in front of the ear, but was clearly demarcated from it by obvious textural differences. Individual hair shafts were about 15 mm in length. The hair was densest just behind the angle of the jaw and the growth extended down just below the lower edge of the horizontal portion of the mandible. The upper and lower lips and chin had no prominent hairy covering. Between the outer ends of the eyebrows and the scalp hair of the temples an outer forehead was found a zone of silky hair, each shaft of which was about 20 mm long. The central part of the forehead had a sparse covering of short soft hairs while the nose, eyelids, and malar areas were without hair. There was slight hairiness of the back and sides of the neck. On the posterior and lateral aspects of the arms, on the extensor aspects of the forearms and on the legs there was a less conspicuous but definite hairiness. Hairs were about 15 mm long and stood at irregular angles on the skin surface.

General Clinical Findings

Teeth—All the milk teeth were said to have been a obvious red or pink colour. Except for the third molar she had a completely erupted set of permanent teeth with a light brown tinting of the crowns. In Wood's light the teeth fluoresced with a soft rose pink colour, and an even more brilliant pink was emitted from the exposed roots when the gums were retracted. On turning down the lower lip the roots of the teeth imbedded in the mandible fluoresced brightly through the gums while the intervening bone did not. Dr M M J Shapiro, who collaborated in the observations is preparing a full report with a review of the subject for the South African dental press.

Bones—In the living subject it is a difficult task to establish the presence of slight pigmentation of the bones by anything less than a biopsy. Among the gentler procedures, Macleod and Garrod's (1926) method of trans illuminating the finger was attempted but proved a failure because of the sclerosis and pigmentation of the soft tissues. Fraenkel (1924) in any case considered the technique unreliable. Inspection of the maxilla and mandible through the mucoperiosteum of the mouth was inconclusive. No definite discoloration of these bones could be seen in sunlight nor did they fluoresce in Wood's light.

Ears, Eyes, and Nose—The upper curve of the helix of each auricle was hyperpigmented; no milia were present. There was a supernumerary tubercle above the tragus on either side. The ear drums were normal. The portion of the bulbar conjunctiva occupying the palpebral fissure was a diffuse yellow brown colour and conspicuously thickened. This thickening extended slightly across the lateral edge of the limbus on either side. In Wood's light these areas fluoresced a bright white, and looked rather like milk-curd. No further abnormalities were noted in the internal or external examination of the eyes. The nasal vestibule was slightly shrunken and inelastic. The bridge of the nose was flat, but the septum was normal apart from a slight deflection.

On rhinoscopy Dr C Aronson reported a clinical picture compatible with an allergic rhinitis. Radiography revealed clouding of the left maxillary antrum attributed to thickening

Fig 2—Relation of delay time to urine flow circles denote P.A.H. average delay time of each experiment shown in the accompanying table, squares denote methylene-blue delay time

Results are shown in the accompanying table and figs 1 and 2

DISCUSSION

The table gives the total delay time from the ante cubital vein to the end of the urinary catheter, this includes (a) the arm to kidney circulation time, (b) the kidney to bladder delay time, and (c) the delay time due to the urinary catheter. We include the last two in "renal tract delay time". With urine flows below 2 ml per minute the five observations we have made seem to indicate an inverse relationship between total delay time and urine flow. But, at such rates of flow, small errors in urine collection may introduce considerable errors in the calculation of delay time and dead space, and we believe that this method of estimation gives only a rough guide, and we have not proceeded further.

With urine flows above 2 ml per minute the method is more accurate, and with flows between 2 and 14 ml per minute total P.A.H. delay time in 14 people was between 1.5 and 3.1 minutes, with an average of 2.4 minutes, and the corresponding dead space was between 5.4 and 30.7 ml. The methylene blue delay time in 5 people ranged from 1.5 to 2.7 minutes, with an average of 2.2 minutes. Allowing a circulation time from arm to kidneys of 12–18 sec, this gives an average renal tract delay time from the kidney to the end of the catheter of about 2.1 minutes.

This unexpected constancy in delay time at rates of urine flow between 2 and 14 ml per minute implies that the renal tract dead space is capable of expanding from 5.4 to 30.7 ml. This is well shown in cases 3, 5, 9, 10, and 15 (see table), on each of whom two observations were made at different rates of urine flow.

The site of this increased capacity of the renal tract at high rates of urine flow is a matter of speculation. The only parts distensible to the required degree are the bladder, the renal pelvis, and possibly the tubules, we tried to measure the bladder dead space in our patients by injecting 5 ml of physiological saline solution into the bladder through the urinary catheter and promptly withdrawing the bladder contents into the same syringe. If the bladder dead space had expanded from 0 to 10 ml, it would be reasonable to expect that the injection of 5 ml of saline would be followed by the withdrawal of 15 ml of saline plus urine. We found that, if the process of injection and withdrawal took x sec, the volume of fluid withdrawn was regularly 5 ml plus the amount of urine formed in x sec, and this process could be repeated. This observation implies that in these cases the bladder dead space approximated to zero and that the renal pelvis and/or the tubules were the site of the renal tract expansion.

SUMMARY

Results are reported on twenty four observations of renal tract delay time and dead space (kidney to end of urinary catheter) in 17 people.

When the urine flow was between 2 and 14 ml per minute, the renal tract delay time (including the urinary catheter) was between 1.3 and 2.8 minutes and averaged 2.1 minutes.

This implies that the renal tract dead space can increase in volume from 5.4 to 30.7 ml. Some evidence is presented suggesting that this increase in volume occurs in the renal pelvis and/or the tubules.

We wish to thank Prof E. P. Sharpey-Schafer and Dr F. T. G. Prunty for the help and facilities they have given us in these observations, and Mr M. G. Ventom for technical assistance.

CONGENITAL PORPHYRIA, HYDROA AESTIVALE AND HYPERTRICHOSIS IN A SOUTH AFRICAN BANTU

G. H. FINDLAY

B.Sc., M.B. Witwatersrand
OF PRETORIA

H. D. BARNES

M.Sc., A.R.I.C.

OF THE BIOCHEMICAL DEPARTMENT, SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH, JOHANNESBURG

Cases of congenital porphyria are still rare enough to warrant reporting. This case has the additional interest of being the first recorded in an African, although other forms of porphyria have been found in that race (Barnes 1945, Barnes, in preparation).

CASE REPORT

The patient, a girl of 13 belonging to the Barolong tribe, was the only child of first cousins. She had three normal half brothers from two other marriages of her mother. Her father had disappeared and could not be traced. Her mother was short in stature but not otherwise abnormal, porphyria was not detected in her urine. No other member of the family had any comparable disease.

History

She is said to have been completely well until the age of 11 months, when her urine became red, and certain skin lesions and an overgrowth of hair appeared on the face. Since then the abnormal colour of the urine has varied in intensity but never entirely disappeared, it has possibly been more obvious in midsummer. Skin lesions have always been present, involving at different times most of the exposed surfaces of the body, to which they have been confined. They were most abundant during mid childhood and have been less numerous for the past year or two. No association has been noted between change of season and the severity of the skin lesions, but the child lives in the Transvaal, where the sunshine is bright throughout the year. Though there is no conclusive evidence that lesions have resulted from knocks or friction, it is stated that the skin tends to break down readily after minor wounds and scratches. Apart from an extension to the limbs the hairy overgrowth has shown no noteworthy change in the recent or remote past.

The relations did not regard the child as abnormal except for the skin condition, and no internal complaints or crises of pain had ever been noted.

Dermatological Findings

The Skin.—Our observations extended intermittently over several months. During this time four bullae were seen or

The examination of the liver (function tests, histology) and electrophoretic fractionation of the serum proteins yielded distinctly abnormal results. These are difficult to evaluate because South African Natives often show pathological values in these tests when judged by European standards. Furthermore these observations were not always made on earlier cases of congenital porphyria, so it would be premature to attach a meaning to them.

The aetiology of the skin lesions remains obscure. The names *hydra aestivale* and *epidermolysis bullosa* have both been used according to whether light or trauma seemed to the user to be predominant in producing bulles. If sunlight is responsible for producing the skin lesions, it is significant that our patient's racial pigmentation offered her no real protection. In at least one case (Gray, Rimington, and Thomson 1948) the effectiveness of these stimuli appeared to alter. In our opinion it is not possible to distinguish separate clinical forms of these cutaneous conditions when they are associated with porphyria and when they occur apart from it. It is likely, therefore, that no causal relationship exists between the skin lesions and porphyria but rather that they are linked genetically. Experiments to demonstrate a causal connection between bulla formation and skin sensitisation by porphyrin have largely failed (Blum 1941).

The trauma of everyday life seemed to be responsible for a measure of the sclerosis and deformity of the hands. In a right handed person this change would be most developed in that hand, and in fact the tips of the right thumb and index fingers showed the greatest degree of sclerotic atrophy. This suggested that we were dealing with a pure traumatic sclerosis which was not a sequel of bulla formation. Brunsting and Mason's (1946) case where the right hand was reported as being more disabled than the left appeared to support this conclusion. Against it stands the persisting suppleness of the soles in spite of far heavier traumatic insults from walking barefoot in the country.

The prognosis in congenital porphyria whether it is treated or not, is difficult to assess. A combination of poverty and ignorance in our patient prevented us from instituting a régime of protection from the sun, and the short course of crude liver injections she was given brought no clinical improvement. Many of the earlier reports indicate that intercurrent pulmonary tuberculosis is a common cause of death. The famous case, Matthias Petry, died at the age of 32. The later history of Gray's (1926) patient is of considerable interest: this girl showed a blood picture not unlike that in our case, and over a period of 4 years the anaemia had slowly advanced. At the request of Sir Archibald Gray, Dr G Stewart Smith, pathologist to the Royal Devon and Exeter Hospital, has kindly furnished the post-mortem findings on her. She ultimately died at the age of 31 with a severe degree of anaemia, and myocardial failure apparently consequent on the anaemia. Sir Archibald Garrod's case, G.L., is known to be still alive and is now in his thirties. We are informed that he has suffered considerable scarring and mutilation despite rigorous precautions against exposure.

SUMMARY

A case of congenital porphyria is described in a Bantu girl of consanguineous parentage. The aetiology, clinical features, and prognosis are briefly discussed.

We are much indebted to Dr Murray, Dr Anderson, and Dr Gullman for the special investigations acknowledged in the text and to the South African Iron and Steel corporation for the lutidine. One of us (G. H. F.) wishes to thank Dr Davison and Dr Winter of the Pretoria Leprosy Institute, for referring the case to him and Dr A. Altmann, paediatrician at Baragwanath Hospital, for facilitating investigations.

INTERSTITIAL INGUINAL HERNIA

REVIEW OF SIX CASES

T. J. NOONAN

M.B. N.U.I.

LATE SURGICAL OFFICER, ST LUKE'S HOSPITAL, ANWA, NIGERIA

MUCH has been written about interstitial hernias, and probably the most complete accounts are those of Lower and Hicken (1931) and Thunig (1943). As the name indicates, they are hernias in which the sac does not follow the usual course found in ordinary inguinal hernias but lies between the various layers of the abdominal wall. Lower and Hicken collected 590 published cases and found that the ratio of male to female was about 4 to 1. Most authorities, however, consider that this ratio is much higher and that interstitial hernia is rare in the female.

ETIOLOGY

It has been held since the days of Krönlein that the aetiological factor is some obstructive condition in the inguinal canal, the commonest cause being maldevelopment or arrested descent of the testis, hence the preponderance in the male. Moynihan (1900) cited Macready's figures of 129 cases, in 67% of which the testis was either completely retained or had only partially descended. Hutchinson (1923) thought that the lax mesorchium of such a testis rendered it abnormally mobile, allowing it to be displaced upwards or outwards by muscular exertion and so produce a pouch of *processus vaginalis* between or behind the muscles of the abdominal wall. Edington (1942), however, reported a case associated with an undescended testis which had, in addition, a scrotal sac.

Other abnormalities which have been noted in association with these hernias are (1) a small external ring, (2) an external ring closed by adhesions due to a badly fitting truss, (3) absence of the cremaster muscle, and (4) superimposition of the abdominal rings. At least one case has been reported where the cause was a hydrocele of the canal of Nuck. At one time it was erroneously believed that forcible and oft repeated efforts at reducing an ordinary inguinal hernia might lead to the formation of an interstitial sac, but such attempts could only lead, when no diverticulum is present, to displacement of the whole sac or rupture of its neck. Displacement of the sac leads to reduction en masse and not a true interstitial hernia.

CLASSIFICATION

McGavin (1932) classified interstitial hernias into (1) those in which an interstitial sac alone is present and (2) those with, in addition, a patent *processus vaginalis*. The generally accepted classification, however, is that of Fuld (1921).

(1) *Properitoneal*—The sac lies between the peritoneum and fascia transversalis. It is usually directed towards the anterior superior iliac spine, but sometimes it may be towards the bladder or even the obturator foramen.

(2) *Inguino-interstitial*—The sac may lie between the various layers of the abdominal wall (a) between the transversalis fascia and the transversalis muscle, (b) between the transversalis and internal oblique muscles, (c) between both

of the mucosa only. The lips were dry, scaling, and inelastic, and the gums were swollen and septic. The buccal cavity generally showed no abnormality.

The liver was clinically normal. Aspiration liver biopsy was performed (Dr M H Shnier), and the specimen submitted to Dr T Gillman who made the following observations. Ultraviolet light microscopy showed no porphyrin in the liver. There was only a fluorescence ascribed to vitamin A. Scherlach R preparations showed a moderate fatty infiltration of the liver cells, but the fat stained an orange colour suggesting that it was present in combination with other organic substances. Slides subjected to the prussian blue test for iron showed fine granular deposits in the liver cells with a certain quantity of iron in "bound" form as shown by green staining. There was no cirrhosis or other disease, but the cytoplasm of the liver cells had a somewhat "washed out" appearance such as Dr Gillman recalled having seen during the recovery phase of pellagra, and also in the livers of cases dying from shock or acute hemorrhage.

The spleen was enlarged to a point 1 in below the left costal margin. Two enlarged lymph glands were felt—one in either axilla—but none elsewhere. Clinically and radiologically the heart and lungs were normal.

Dr R Geerling, neurologist, confirmed the fact that the central and peripheral nervous systems were intact. The child was shy but intelligent.

Endocrine Glands—The pituitary fossa was radiologically normal, the thyroid was normal to palpation, there was no radiological evidence of thymic enlargement, and abdominal examination revealed no masses to suggest adrenal or ovarian neoplasm, or indeed any other disease. The urinary 17 ketosteroid excretion was within normal limits. The external genitals were not abnormal, the menarche had not yet occurred, and the breasts were undeveloped.

Laboratory Investigations

The icteric index was normal and the van den Berg reaction negative. The thymol turbidity test yielded a result of 3.5 units, the thymol flocculation test was + positive, and Ucko's modification of the Takata-Ara reaction +++ positive. Serum albumin was 4.6 g and serum globulin 4.4 g per 100 ml. Electrophoretic analysis of another specimen of serum by Mr C G Anderson showed the following percentage distribution: albumin 43 (normal average 59), α globulin 8.4 (n.a. 14), β globulin 13.2 (n.a. 14.3), γ globulin 35.5 (n.a. 11.8). Serological tests for syphilis were negative. The blood serum showed no fluorescence suggestive of porphyrin.

Bone marrow and blood—Smears of the bone marrow fluoresced an orange colour under the ultraviolet microscope. It was impossible to decide where this fluorescent substance (porphyrin) was situated.

Dr J F Murray reported that the bone marrow was hypercellular (total nucleated cells, 185,500 per c.mm.). There was an increase in normoblasts (22.4%). There was also a slight myeloid and erythroid preponderance (myeloid/erythroid ratio, 1.9:1, myeloid/lymphoid ratio, 8.6:1). In other respects the marrow was normal (Murray 1949). The peripheral blood showed slight anaemia and leucopenia, with 2 normoblasts per 100 leucocytes. Red cells 4,300,000 per c.mm., Hb 12.1 g per 100 ml, white cells 3500 per c.mm. (neutrophils 68, monocytes 6, lymphocytes 26), packed cell volume 36, reticulocytes 1.8%. No punctate basophils or increase in diffuse polychromasia was observed.

Urine—Routine examination of the urine gave normal results. Its colour varied in successive specimens between cherry red and deep burgundy. On standing, some darkening occurred.

Direct spectroscopic examination of the urine showed a fairly intense absorption band at about 500 m μ and two other bands in the green suggestive of a metal porphyrin complex. No band could be seen in the red. On adding hydrochloric acid the spectrum changed to that of acid porphyrin. On adjusting the pH of the urine to 3.1 with hydrochloric acid a dark flocculent precipitate soon formed which was collected by centrifuging. The supernatant urine was distinctly less red than the original and a deep layer showed complete absorption of the violet and blue and a narrow band at 625 but no absorption in the green. In a 1 in tube a strong band at 500 was seen. The intense band at 500 which persisted after flocculation of the porphyrin was out of proportion to the weak Schlesinger reaction for urobilin. The porphobilinogen reaction was repeatedly

negative, even in an alkaline urine obtained after oral administration of a potassium citrate mixture.

The dark flocculent precipitate was treated with acetic acid and shaken with ether which removed some of the pigment. Both fractions were dissolved in hydrochloric acid and ammonia added cautiously until flocculation occurred. The precipitates were separated by centrifugation, drained, washed with distilled water and dissolved in dilute ammonia. From both these solutions chromatograms were made on paper strips (Nicholas and Rimington 1949) and fluorescent spots were shown at the following Rf values:

Ether-soluble			0.30	0.44	0.56	0.79
Insoluble	0.12	0.18	0.30	0.46	0.58	

The bold figures represent strongly fluorescent spots, all the rest were faint or very faint.

Porphyrin was recovered in the above manner from about 3 litres of pooled urine. The absorption bands of the ether insoluble fraction were measured in acid and alkaline solutions by means of a Hartridge reversion spectroscope:

In 2N HCl	552	574	595 m μ
In 10% NaOH	507	541	573 614 m μ

Methyl esters were prepared from both fractions of the porphyrin and after two recrystallisations the uroporphyrin ester melted at 288°C and the coproporphyrin ester at 245–247°C. The mother liquors which still contained porphyrin esters were kept but not further examined.

Stools—About 50 g of formed stool were dried with acetone and the residue extracted three times with acetic acid ether (1:4). This extract was washed with water and the porphyrin removed by several successive extractions with 2N hydrochloric acid. After passing back and forth from ether to acid several times a strip chromatogram showed fluorescent spots with the following Rf values:

Faecal porphyrin	0.66	0.70	0.78
Ether soluble porphyrin from urine	0.62	0.69	0.74

Our "lutidine," a gift from the South African Iron and Steel Corporation, was a complex mixture of tar bases boiling over a wide range. In consequence its behaviour was less uniform than that used by Nicholas and Rimington (1949) and chromatograms run on different days showed considerable variation.

The spectra of the faecal porphyrin measured in acid and alkaline solution with the reversion spectroscope were:

In 2N HCl	548	581	591 m μ	
In 10% NaOH	508	543	571	617 m μ

Typical coproporphyrin I methyl ester crystals melting at 245°C were obtained in the usual manner. The mother liquor was not further examined.

The above findings correspond with those reported in other cases of congenital porphyria—namely, uroporphyrin I and coproporphyrin I predominating in the urine and coproporphyrin I in the stool.

DISCUSSION

Our case raises no problems in diagnosis or classification. The biochemical findings and the pigmentation of the teeth are typical of congenital porphyria as described in the original classification of Hans Gunther (Garrod 1923). The skin lesions are also typical of hydraea aestivale, which, since McCall Anderson's (1893) time, has been known to be associated with porphyrinuria. If one excludes adult cases with skin lesions and porphyria, where the bones and teeth are unpigmented and the porphyrin excretion appears to be less abundant, the congenital type is seen to be by far the least common type of porphyria.

Our case corresponds most closely with the girl described by Sir Archibald Gray (1926), who too exhibited an overgrowth of hair. Hypertrichosis is an unusual finding in congenital porphyria, and it may have a genetic basis in view of the normality of the endocrine glands. Furthermore, in all the reported instances of hypertrichosis and porphyria we know of, the cases were women. This stands in contrast with the usual predominance of men affected by the genetically recessive form of hydraea aestivale and porphyria.

Mackey and Garrod (1920) observed that splenomegaly is usually first detected in the second decade or slightly earlier, our findings agree with this.

The examination of the liver (function tests, histology) and electrophoretic fractionation of the serum proteins yielded distinctly abnormal results. These are difficult to evaluate because South African Natives often show pathological values in these tests when judged by European standards. Furthermore these observations were not always made on earlier cases of congenital porphyria, so it would be premature to attach a meaning to them.

The aetiology of the skin lesions remains obscure. The names hydroa aestivale and epidermolysis bullosa have both been used according to whether light or trauma seemed to the user to be predominant in producing the bullae. If sunlight is responsible for producing the skin lesions, it is significant that our patient's racial pigmentation offered her no real protection. In at least one case (Gray, Rimington, and Thomson 1948) the effectiveness of these stimuli appeared to alter. In our opinion it is not possible to distinguish separate clinical forms of these cutaneous conditions when they are associated with porphyria and when they occur apart from it. It is likely, therefore, that no causal relationship exists between the skin lesions and porphyria but rather that they are linked genetically. Experiments to demonstrate a causal connection between bulla formation and skin sensitisation by porphyrin have largely failed (Blum 1941).

The trauma of everyday life seemed to be responsible for a measure of the sclerosis and deformity of the hands. In a right handed person this change would be most developed in that hand, and in fact the tips of the right thumb and index fingers showed the greatest degree of sclerotic atrophy. This suggested that we were dealing with a pure traumatic sclerosis which was not a sequel of bulla formation. Brunsting and Mason's (1946) case where the right hand was reported as being more disabled than the left appeared to support this conclusion. Against it stands the persisting suppleness of the soles in spite of far heavier traumatic insults from walking barefoot in the country.

The prognosis in congenital porphyria whether it is treated or not, is difficult to assess. A combination of poverty and ignorance in our patient prevented us from instituting a régime of protection from the sun, and the short course of crude liver injections she was given brought no clinical improvement. Many of the earlier reports indicate that intercurrent pulmonary tuberculosis is a common cause of death. The famous case, Matthias Petry, died at the age of 32. The later history of Gray's (1926) patient is of considerable interest: this girl showed a blood picture not unlike that in our case, and over a period of 4 years the anaemia had slowly advanced. At the request of Sir Archibald Gray, Dr G Stewart Smith, pathologist to the Royal Devon and Exeter Hospital, has kindly furnished the post mortem findings on her. She ultimately died at the age of 31 with a severe degree of anaemia, and myocardial failure apparently consequent on the anaemia. Sir Archibald Garrod's case, G.L., is known to be still alive and is now in his thirties. We are informed that he has suffered considerable scarring and mutilation despite rigorous precautions against exposure.

oblique muscles, or (d), rarely, between the fibres of the internal oblique muscle

(3) *Inguino superficial* (Küster's hernia)—The sac lies between the external oblique and Scarpa's fascia. The sac may go laterally towards the anterior superior iliac spine, upwards and medially, or downwards over the femoral ring

The only published statistics on the relative frequency of each type of interstitial hernia are those of Lower and Hicken (1931), who in their series of 590 cases found 119 of the properitoneal type, 348 of the inguino-interstitial type, and 123 of the superficial type. Biasini (1948) reviews his experience with 3 cases of the properitoneal type, which represent 0.31% of the hernias encountered at his clinic

ANATOMY OF THE SAC

Moynihan (1900) has stated that bilocular sacs must be present. Wilensky and Gordon (1939), however, state that about a third of the recorded cases have monolocular sacs. In many inguinal hernias, especially scrotal ones, there is a secondary locus in the region of the internal ring, but this by itself does not constitute an interstitial hernia. A true interstitial hernia must have a sac large enough to burrow its way between the layers of the abdominal wall. In bilocular sacs the shape is always that of an hour glass, and there is a common opening into the abdomen at the neck of the sac. Biasini (1948) claims that in some cases there may be distinct openings, usually close together. The interstitial portion is to be regarded as a diverticulum of the primary sac (Thunig 1943)

DIAGNOSIS

The diagnosis of interstitial hernias has presented great difficulty in the past, chiefly owing to lack of knowledge of the condition. Properitoneal hernias are the most difficult to diagnose and are rarely diagnosed preoperatively even when strangulated. The other types, if reducible, are readily diagnosed, but it is impossible to distinguish between type 2 (c) and type 3. Trouble arises when they become strangulated. A strangulated properitoneal hernia is almost impossible to diagnose as such, usually the most that can be said is that there is an acute obstruction. Strangulation of the inguino-interstitial or the inguino-superficial types, if on the left side, may be mistaken for carcinoma of the colon with acute obstruction or even for a tumour of the abdominal wall. A typical strangulated interstitial hernia shows signs of acute obstruction, a mass is present above Poupart's ligament, and the testis on the same side as the lump is absent from the scrotum. In such a case the diagnosis is easy if one considers the possibility of interstitial hernia. In a properitoneal hernia a lump is rarely palpable, hence the difficulty of diagnosis. The reason for failure to diagnose interstitial hernias has been summed up by Beigler and O'Brien (1928)

"It is seldom we make a preoperative diagnosis of other than the above types (direct and indirect) largely because we fail to recognise any other type of inguinal hernia. This failure of recognition is probably due to the fact that most of us are unaware of the existence of inguinal hernias other than the usual types"

PERSONAL EXPERIENCE

In three years, at St Luke's Hospital, Anua, Uyo, Nigeria, I operated on 4 simple and 2 strangulated interstitial hernias out of a total of 482 inguinal hernias. The 4 simple ones were all in adult male patients and were inguino-interstitial type (c)—i.e., the interstitial sac lay between both oblique muscles. In each case the sac extended out towards the anterior superior spine. In 1 case it approached to within an inch of the lower right costal margin in the anterior axillary line. In no case

was there obstruction, the testes being normal and the external rings dilated. In 3 cases there were bilocular sacs, large scrotal hernias being associated with the interstitial sac. One patient had a monolocular sac but the external ring was sufficiently dilated to admit two fingers. Diagnosis was obvious in each case, small intestine, which was readily reducible, being palpable almost under the skin. No difficulty was encountered in freeing the interstitial sac through the usual inguinal incision.

The 2 strangulations were in a man and in a woman. The man had a properitoneal sac, and the woman an inguino-interstitial type (c).

Case 1—A man, aged about 30, was admitted for repair of a left inguinal hernia. Examination on admission showed nothing abnormal on the right side. Later he complained of mild circumumbilical pain not associated with nausea or vomiting. Examination revealed nothing unusual. The pain persisted and became colicky, and after twelve hours the patient vomited once. An enema produced a moderate result, a second given an hour later was retained. Acute obstruction was diagnosed, and operation performed under 'Nupercaine'.

Operation—A lower right paramedian incision revealed a mass the size of an egg in the region of the right internal ring. An inguinal incision was then made, and a unilocular properitoneal sac containing strangulated ileum was discovered. Division of the neck of the sac led to the return of the normal colour of the bowel. The sac was removed at the level of the inferior epigastric vessels, and no repair was made. The left side was operated on at a later date and the patient was subsequently discharged in good health.

Case 2—A woman, aged about 40, was admitted with four days' abdominal pain, vomiting and constipation. Examination showed much abdominal distension, and a tender lump was palpable in the right inguinal region between the anterior superior spine and the external ring but not coming through the latter. Despite the fact that the patient had vomited many times she was not much dehydrated. Her tongue, though dry, had not the rasp like feel observable in cases of late strangulation, and her urinary chlorides though diminished were still present. The patient received 1000 ml of saline solution intravenously and was treated by Wangenstein gastric suction preoperatively. A strangulated interstitial hernia was diagnosed, and operation was done under local analgesia.

Operation—The usual inguinal incision was made, and an inguino-interstitial sac type (c) containing strangulated ileum was found. The bowel was gangrenous and 6 in. of it was resected. A side to side antiperistaltic anastomosis was made, and the distal end closed. Since the bowel wall was oedematous, the proximal end was left open and brought to the surface to decompress the suture line (a modification of McKenna's (1947) technique). Fourteen days later the ileostomy was closed and returned to the abdomen under thiopentone anaesthesia. The canal was subsequently repaired, and the patient was discharged in good health.

SUMMARY

Interstitial hernias, though unusual, are liable to be met with in any large series of cases.

Apart from those which are properitoneal the diagnosis is easy.

Two cases of strangulated interstitial hernia are reported in detail.

from the *Pædiatric Clinic of the Caroline Institute, Norrullas Hospital, and the Central Municipal Bacteriological Laboratory, Stockholm*

It is commonly accepted that the antibodies which normally appear in the foetus in utero are passive and transmitted from the mother through the placenta. This view is supported by the close relationship between maternal and foetal titres at term for some types of antibodies, and by the comparatively rapid fall in the child's titres after birth.

Antigens are believed not to pass the intact placental barrier. A transfer of antigen from foetus to mother in this immunisation has been attributed to a local lesion of the villi. Such lesions have been demonstrated in serial sections of normal placenta (Naeslund and Arén 1947, Kline 1948) and in experiments with tagged erythrocytes (Naeshund 1950).

The facts so far known about the relationship between maternal and foetal antibody titres at term are shown in table 1.

The fact that the human placenta, like that of monkeys and rodents, is permeable to antibodies, whereas the placenta of ruminants, horses and pigs is not, has been attributed to the difference in the number of layers of cells separating maternal and foetal blood (Ratner et al 1927). But this cannot explain why some types of antibodies pass over more easily than others in man (table 1). Differences in molecular size and shape of different antibodies are probably relevant, there may be a threshold mechanism preventing the passage of antibodies present in very low concentrations, and one cannot be certain that the passage of antibodies does not involve more complicated and more active processes than mere filtration whose speed is determined by the thickness and pore size of the placental barrier.

We have not found any report of investigations dealing with the development of the antibody titres in the human foetus before term.

In Sweden legal abortion provides an opportunity for the study of antibodies in the foetus at an early stage of gestation. From the antibody titres in premature infants and in those born at term one may obtain information concerning conditions in the late stages of gestation. In this paper we report our results as regards antistreptolysin

and antistaphylolysin. Studies are now in progress along similar lines with other antibodies—e.g., iso agglutinins and diphtheria antitoxin.

MATERIAL AND METHODS

Antistreptolysin and antistaphylolysin titres were estimated in mother and foetus (or infant) in 24 cases between 16 and 22 weeks (16 being between the 18th and 20th week), in 14 cases between 30 and 39 weeks, and in 15 cases at term.

The legal abortions were done by abdominal section. Blood from the foetus was obtained by heart puncture. In most cases the indication for operation was either sociomedical or eugenic. The samples from children born prematurely or at term were collected from the cord.

Antistreptolysin titres were estimated by the technique described by Ipsen (1944), and antistaphylolysin titres by that of Packalén and Bergqvist (1947). One of us has previously reported on the normal values for antistreptolysin titres obtained with the same technique in adults (Lagercrantz 1948).

RESULTS

The results are summarised in table II, which shows a considerable difference in the titres of mother and foetus between the 16th and 22nd week. For antistreptolysin the ratio in individual cases ranged from 200:6 to 100:25. The antistaphylolysin titre in the mothers varied from <0.25 to 2.8, but in the foetus it was never measurable with certainty, the difference between mother and child may of course have been as great as for antistreptolysin, but the "normal" level is too close to the minimal demonstrable level to show this.

In agreement with the observations of Timmerman (1931), Wilson et al (1934), Gordon and Janney (1941), Bryce and Burnet (1932), and Vignes et al (1948) determinations at term show closely corresponding levels in mother and infant. Exceptionally the level in the infant seems to be definitely higher than in the mother.

It is of special interest to find out to what extent premature infants are provided with transmissible antibodies. Since the level may depend on the degree of prematurity, our findings in this group are shown in table III with the duration of gestation in each case. It will be seen that the antistreptolysin titres in mother and infant closely correspond even in the most premature cases. The antistaphylolysin titres, on the other hand, tend to be somewhat lower in the infant in the most immature cases, though, with one exception (case 7), the difference is not very striking.

TABLE II—NUMBERS OF MOTHERS AND FETUSES (OR INFANTS) AT DIFFERENT PERIODS OF GESTATION FOUND TO HAVE VARIOUS TITRES OF ANTISTREPTOLYSIN AND ANTISTAPHYLOLYSIN

* The reading was less than, but nearly equal to, this figure.

DISCUSSION

According to Grosser's classification, the human placenta belongs to the haemochorial type. Only two layers of cells separate the blood of the mother from that of the foetus. During pregnancy the contact between the two vascular systems becomes successively more intimate, the trophoblast layer decreasing in thickness, the surface of the villi growing relatively as well as absolutely, and the number of foetal capillaries within the villi multiplying.

Using radioactive tracers Flexner et al (1948) and Hellman et al (1948) have shown that the exchange of sodium and water between mother and foetus increases continually up to the last month of gestation. The passage of sodium, calculated per unit weight of placenta, increases seventyfold from the 9th to the 36th week of gestation in man. Immediately before term the ratio between the amount of sodium transferred to the foetus and the amount retained was about 1:130—i.e., there was an extremely high "safety factor".

The molecular weights of the antibodies are very high, most of them belonging to the γ globulin fraction of the plasma with a molecular weight of about 150,000. It is impossible to compare the permeability of the placenta for electrolytes with that for antibodies.

The results presented here show that antistreptolysins and antistaphylolysin are present in very low or undetectable concentrations in the human foetus between the 16th and 22nd week of gestation. In a group of premature infants born at 30-39 weeks, there was already a close correspondence between the titre in the mother and in the infant for antistreptolysin, whereas the figures for antistaphylolysin were somewhat lower in the infant in some of the most premature cases. In agreement with earlier workers we observed a close correspondence for both types of antibodies in the infants born at term.

Many of the antibodies in human blood are found in the γ globulin fraction of the plasma, the level of which is about 1 g per 100 ml. Since the antibodies form only a minor part, it must not necessarily be assumed that alterations in the concentrations of one or several antibodies as observed by serological methods must be reflected in alterations of the γ globulin fraction determined by physicochemical methods. Nevertheless it is of interest in this connection that Moore et al (1949), in investigations on the serum from six human foetuses at 3-9 months, noted a continuous increase of the γ globulin fraction from very low to high normal values.

SUMMARY

The close correlation in the titres for antistreptolysin and antistaphylolysin between mother and child at term is established in the second half of gestation.

An analysis of the conditions in 24 fetuses aged 12-22 weeks showed consistently lower values in the fetus than in the mother (table II)

Children born prematurely (between the 30th and 41st week) already showed a close correspondence between foetal and maternal titres for the antistreptolysin, if not quite so good for the antistaphylolysin (table III)

We thank the chief physicians of the maternity clinics at the Sabbatsberg Hospital, Prof P Wetterdahl, and the Mäanna B.B., Docent S Karlson, for their kind co-operation in collecting the material. Mrs Lekeberg assisted carefully in the laboratory work.

It is generally accepted that children are especially liable to suggestion. As to suggested actions, this is partly due to their impulsiveness but as to suggested ideas and beliefs it is partly due to their ignorance. Thus there are rational grounds for the suggestibility of children to which some psychologists do not give adequate attention. Children usually accept for example, the statements of their parents, believing even some fairy tales with readiness. One reason is that they have little on which to base any criticism of the ideas. They also tend to find such stories lively and pleasing so that a friendly and pleasant mood is established in which the tendency to accept and believe is strong for we are naturally more critical and suspicious when unhappy. But there is another good reason why children should be more suggestible. So many things have been told a child without evidence by his father or mother, which he has later found to be true—all the many little facts of everyday life about which he receives instruction so that he not unreasonably comes to the conclusion that everything told him by grown-ups will be true. Later however he becomes more critical. He finds some stories false. —Prof C W VALENTINE, D. PHIL., *Psychology and its Bearing on Education* London, 1950, p 101

OBSTRUCTION OF THE INFERIOR VENA CAVA BY A LEIOMYOSARCOMA

N J ROUSSAK

B Sc, M B Manc, M.R.C.P.

MEDICAL REGISTRAR, MANCHESTER ROYAL INFIRMARY

J D HEPPLESTON

M B Manc

ASSISTANT LECTURER, DEPARTMENT OF PATHOLOGY, MANCHESTER UNIVERSITY

OBSTRUCTION of the inferior vena cava is uncommonly diagnosed and even more rarely confirmed during life. The aetiological basis in the case to be described was a pathological rarity.

CASE REPORT

A 60 year-old man was admitted to the Manchester Royal Infirmary under the care of Dr A H Holmes on Dec 20, 1948. He complained of progressive swelling of the lower limbs and back over the last 6 weeks. This had commenced above the right ankle, spreading shortly afterwards to the left side, and within about 3 days both lower limbs were affected up to the groins. There had been transient aching pain in the lumbosacral region which had ceased when he went to bed. With rest the swelling partially subsided over the next 5 weeks. The patient stated that he was otherwise in good health, and had not lost weight.

He was a sparely built man with moderate oedema of both lower limbs, more marked on the left side. The buttocks and sacral region were also oedematous, but not the abdominal wall. There were two rather tense veins about 2 mm in diameter on the anterior surface of the right leg below the knee. Other physical findings were normal.

During the next month a left sided varicocele developed and a prominent vein appeared over the right costal margin anteriorly, the blood flow in which was upwards. A spontaneous diuresis was noted soon after admission and this continued for about a month, the oedema diminishing. No albuminuria was found although the urine was frequently examined. On admission the blood-count was red cells, 4 490 000 per c mm, Hb 84%, colour index 0.93, white cells 8000 per c mm with a normal differential count. Serum-albumin was 3.2%, serum globulin 2.6%, and serum alkaline phosphatase 14 units per 100 ml. Microscopy of the urine did not show any abnormality. On Jan 6 the serum-alkaline phosphatase rose to 17 units per ml and on Jan 19 to 22 units. X-ray films of the chest, skull and dorsolumbar spine were normal but that of the pelvis revealed a small area of mixed sclerosis and translucency in the superior ramus of the left pubis which was interpreted as either a metastasis or localised Paget's disease. An intravenous pyelogram suggested an abnormality of the left kidney but the retrograde pyelogram did not confirm this.

It was clear that the physical findings and investigations did not point to any of the common causes of oedema and by a process of exclusion a provisional diagnosis of obstruction of the inferior vena cava was reached. On Jan. 6, Prof A M Boyd carried out venography injecting 20 ml of 30% diodone into the right femoral vein, which was found to be partially thrombosed. The venogram (fig 1) showed no evidence of filling of the inferior vena cava the dye

Fig 1—Venogram (tracing of X-ray photograph). The inferior vena cava is not outlined. An enlarged ascending lumbar vein is seen on left.

Fig 2—Drawing showing tumour (A) inferior vena cava (B), and posterior surface of aorta (C)

outlining veins in the abdominal wall and also a large venous channel 1.25 cm in diameter, lying over the transverse processes of the lumbar vertebrae on the left side. The latter was interpreted as an enlarged ascending lumbar vein. The patient, who had hitherto felt well, suddenly vomited on Feb 1 and again the next day, but had no pain. The edge of the liver was now felt about 2.5 cm below the right costal margin, it was non tender, firm, and smooth. There was no jaundice, the spleen was not felt, and ascites was not present. He became unconscious without other changes in the physical findings, and died the following day.

Post mortem Findings

At necropsy (J D H) the abnormalities discovered were limited to the inferior vena cava, liver, and pubis.

The inferior vena cava was grossly dilated from its origin to the diaphragm. Within it, and causing complete occlusion, was a sausage shaped tumour 17.5 cm long and 2.5 cm wide, with a smooth greyish red surface (fig 2). The tumour could not be separated from the upper part of the abdominal vena cava, it did not spread down the renal veins. The right spermatic vein was also dilated and filled with uniform dark red clot. Both iliac veins were of small diameter with thickened walls and a lumen could not be demonstrated satisfactorily.

The liver, which weighed 1325 g, showed marked passive venous congestion, and the hepatic veins were filled with homogeneous dark red clot. The kidneys were not congested, there were two or three enlarged vessels passing from the renal capsule to the perirenal tissue on each side. The spleen was congested and weighed 130 g. The superior ramus of the left pubis was thickened.

Histology—The tumour was a leiomyosarcoma, consisting of interweaving bundles of smooth muscle cells which in one part showed malignant pleomorphism (fig 3), the cells varying in size and shape and the ratio of nucleus to cytoplasm being increased. The nuclei were also irregular, some being multilobular and others showing mitosis.

In other parts the cells were more regular and loosely arranged with occasional intercellular haemorrhages. The vessels within the tumour consisted of a layer of endothelial cells supported by a small amount of fibrous tissue. The liver showed intense venous congestion which extended to the periphery of the lobules, with centrilobular necrosis and fatty changes in the mid zones, there was no organisation of the hepatic venous clot. The kidneys showed no evidence of venous

obstruction. The thickened pubis was a localised area of Paget's disease.

DISCUSSION

Sporadic cases of obstruction of the inferior vena cava were recorded during the last century, Battle (1887) reporting 3 cases and describing fully the variability of the clinical picture. One of the first large series to be reviewed was that of Pleasants (1911) who collected 296 cases from the literature and added 18 from the Johns Hopkins Hospital records. Of these, 54% were due to thrombosis (over half of which were secondary to puerperal sepsis and other infective states) and 25% were associated with neoplasms.

The following causes of obstruction of the inferior vena cava have been given:

- 1 Pressure on the vein by tumours of pancreas or kidney, retroperitoneal sarcoma, aortic aneurysm, syphilitic liver, ascites, or enlarged glands. The obstruction is often completed in such cases by thrombosis.

- 2 Disease of the wall of the vein, including syphilitic and tuberculous phlebitis and neoplasia.

- 3 Obstruction within the lumen, due to thrombosis originating in the vein or spreading into it from iliac or pelvic veins or hepatic veins in cirrhosis, or to extension of new growth along the renal or suprarenal veins in primary malignant disease of these organs. Reports have been collected of 51 cases secondary to hypernephroma, usually of the left kidney (Ney 1946). Thrombosis may be primary or secondary to infectious diseases (typhoid, puerperal sepsis), distant neoplasia, or trauma.

Classical symptoms of obstruction of the inferior vena cava are oedema of the lower part of the body and the development of engorged, sometimes varicose, veins on the abdomen, flanks, lumbar region, and lower extremities, in which the direction of blood flow may be shown to be upwards. Ascites is not a sign of this condition. Disease processes in general, however, do not always present the classical picture, and the subject under discussion is no exception. The degree and extent of oedema depend on the completeness and rapidity of onset of the obstruction, sudden obstruction tending to cause more oedema than a gradual onset, which allows time for collateral vessels to dilate. Oedema may last a considerable time and lead to ulceration of the legs, or it may soon abate if an efficient collateral circulation becomes established. In our patient the spontaneous diuresis with lessening of the oedema was striking. The distribution of the oedema may be atypical, sometimes affecting only one lower limb, possible reasons advanced

Fig 3—Photomicrograph showing malignancy ($\times 500$)

for this being previous thrombosis of the femoral or iliac vein on the non œdematous side with establishment of a collateral circulation, and congenital venous abnormalities

The collateral circulation to the superior vena cava has been well described by Welch (1909) and Keen (1941), the superficial veins concerned being the inferior and superior epigastric, the long thoracic, the superficial circumflex iliac and the external pudendal, and the deep, the azygos, hemoazygos, and lumbar veins. There may be also some return via the liver, through the anastomoses between the tributaries of the portal vein and inferior vena cava. Engorged superficial veins are not always found at an early stage and may even be absent throughout, a very efficient deep collateral circulation sufficing. In the present case they were almost within the normal range up to the time of death. In difficult cases abnormal venous channels may be demonstrated by infra red photography and venography (Stowers and Grossman 1946). The enlarged left ascending-lumbar vein seen in the venogram in our case may perhaps be the "left inferior vena cava," the embryological counterpart of the normal right inferior vena cava (Keen 1941).

The results of therapeutic ligation of the inferior vena cava are of interest. It was probably first performed by Trendelenburg in 1911 in a patient with puerperal sepsis and has been used more often in recent years to prevent repeated pulmonary embolism. It is stated by some that the procedure does not cause more than slight disability and this only in a few cases, œdema being absent or transitory and enlarged collateral veins only rarely developing (Wakefield and Mayo 1934). Others, however, have found troublesome œdema more often.

The difficulty of diagnosis in many cases of inferior vena caval obstruction is evident when it is considered that it was made during life in only 4 of 18 of Pleasants's cases from the Johns Hopkins Hospital, in 1 of 15 reported from the Mayo Clinic (Judd and Scholl 1924), and in 2 of 10 in another series (Ney 1946).

Certain complications of obstruction of the inferior vena cava may cause death. It would be expected that if the renal veins were occluded heavy albuminuria, perhaps hæmaturia, and renal failure would develop and this may happen if the obstruction occurs suddenly, but otherwise albuminuria appears to be uncommon (Welch 1909), and the anastomosis of veins in the renal capsule with tributaries of the azygos usually enables the kidneys to function normally. This was shown in rats by Addis and Lew (1939) who tied off the inferior vena cava above the level of the renal veins and found that many of the animals recovered from the uræmia that usually resulted. Although in our patient the tumour extended both above and below the entrances of the renal veins albuminuria was never found. Extension of the tumour to involve the hepatic veins may lead to a form of Chiari's syndrome, with tender enlargement of the liver, jaundice, ascites, and splenomegaly. Hepatic enlargement was noted 2 days before our patient died, and at post mortem there was considerable venous congestion of this organ with centrilobular necrosis, although the tumour did not actually block the hepatic veins. Nevertheless uniform red clots were found in them and it is conceivable that death was in fact due to hepatic failure.

Leiomyoma is a fairly common tumour being found in the gastro intestinal and genito urinary tracts, and the uterus, breast, and skin. Leiomyosarcoma, on the other hand, is more rare. It has been reported as a primary tumour in the stomach, duodenum (Golden and Stout 1941), uterus, kidney, and mediastinum (Willis 1948). We have studied the published reports and been able to find only one definite case of leiomyosarcoma of the inferior vena cava.

by Puig Sureda et al (1947) in which it arose from the superior left colic vein. The origin of primary tumours of the inferior vena cava can be two in the German literature of the last century. One of these (Perl 1871) caused complete obstruction of the vein below the hepatic veins, and displaced the vessel like the tumour in our patient, it was called a spindle celled sarcoma but contained muscle fibres, and Virchow seems to have thought that it could be called a myosarcoma. The other (Unruh 1896), an endothelioma.

SUMMARY

A case of leiomyosarcoma of the inferior vena cava is described. The clinical aspects of obstructive disease of the inferior vena cava are reviewed, with special reference to those of primary origin.

Our thanks are due to Dr A. H. Holmes for his advice, and for permission to publish this case. We also wish to thank Prof A. M. Boyd for his criticism, and Dr L. Mead for his advice and criticism, and Dr L. Mead with Spanish publications. We are indebted to Dr J. Davison for fig. 2, and Mr F. Ward for fig. 3.

MELÆNA FROM HETEROTOPIC GASTRIC MUCOSA IN THE ILEUM

EDRIC WILSON

F.R.C.S.

SURGEON, PLYMOUTH, SOUTH DEVON, AND EAST OF ENGLAND GENERAL HOSPITALS GROUP

MELÆNA as a symptom of ulceration of gastric mucosa in Meckel's diverticulum is well known, but it is not so well known that it can arise from heterotopic gastric mucosa in the small intestine.

Brown and Pemberton (1936) state that solitary ulcer of the ileum has been noted not infrequently in necropsy in fifteen years, and in cases, the patients being aged 20-60. The symptoms were abdominal pain in the umbilical region and pallor. The ulcer was found in the 5-90 cm. of the ileum in 9 cases, and midway between the duodenum and the cæcum in 1 case. Microscopically they were simple ulcers with or without a tenacious fibrinous exudate. Brown and Pemberton (1936) state that in cases of bleeding from Meckel's diverticulum but mention no case of gastric mucosa in the diverticulum associated with a simple ulcer of the ileum.

Because of the similarity in symptoms the references to heterotopic gastric mucosa in Meckel's diverticulum are of interest. Hallendorf and (1947) describe ulceration in Meckel's diverticulum by heterotopic gastric mucosa. Sibley (1944) states that Meckel's diverticulum is the most common site of heterotopic gastric mucosa, and thinks that the mucosa of the small intestine becomes progressively more sensitive to gastric acid and pepsin the farther it is from the stomach. He uses the term "dispepsia Meckelii" to describe the condition.

describe perforation of the ileum opposite a Meckel's diverticulum. Matt and Timpone (1940) found that heterotopic mucosa was often present in the neck of the sac and extended into the adjacent ileum, and regard it as a disease of childhood.

CASE RECORD

A married woman, aged 46, was admitted under my care on March 3, 1949, having passed a considerable amount of blood per rectum four hours before admission. She was previously admitted to a medical ward in 1947 with the history that in 1944 she had undergone hysterectomy for fibroids, for a few months she had had a nagging pain in the lower abdomen, and on two occasions had passed blood per rectum, and on the day of admission she had fainted five times following a sudden urge to defecate, and passage of a great deal of blood. On admission there were no abnormal physical signs in the abdomen, but dark-red blood was present

Fig 1—External view of portion of ileum removed
Fig 2—Internal view of portion of ileum removed

in the rectum. The haemoglobin was 55%. Palliative treatment was given. A fortnight later a sigmoidoscopy showed no abnormality. After a month in hospital, in which there was no obvious bleeding but occult blood was found in the stools, she was discharged.

On readmission in 1949 she had been having "windy" pains in the lower abdomen for several weeks and passing much wind. There was some tenderness over the descending colon with general distension of the abdomen, and shortly after admission she passed another 6 oz of blood. She was given enough morphine to keep her sleepy and the bleeding soon ceased.

Progress—Three days after admission there was very slight tenderness just to the right of the umbilicus. There was no history suggesting peptic ulceration, and the appendix had been removed at the previous operation. Haemorrhage from ulceration in a Meckel's diverticulum was considered probable and, since the bleeding had been recurrent, unexplained and likely to endanger life, exploration was thought advisable.

Operation—Laparotomy through a right paramedian incision showed that the appendix had been removed. There was no sign of gastric or duodenal ulcer, and no Meckel's diverticulum was found. In the ileum, 18 in from the ileo-caecal junction, three constricting rings reduced the diameter to about half the normal (fig 1); the pathology was not clear, but it did not look like regional ileitis. Light inches of ileum was resected and end to end anastomosis performed. No other abnormality was found in the abdomen. The patient made an uninterrupted recovery, and she remains well.

Pathology—The specimen removed at operation was a piece of small intestine 4 in long with mesentery attached. It had an hour glass constriction 1 in long, marked externally by three narrow circular whitish bands just visible in the serosa, $\frac{1}{4}$ in apart. Running transversely across the gut in the middle of the constricted area was an annular groove-like defect in the mucosa about 2 mm wide. The edges of the defect were regular, and its floor was formed by smooth shiny oedematous submucosa. The wall of the gut deep to the defective part was just perceptibly indurated. On either side of the groove the mucosa was hypertrophic and presented an irregularly folded pattern quite distinct from the regular ring-like folds of normal mucosa. At one point $\frac{1}{4}$ in away

Fig 3—Mucosa near annular defect. (x30)

from the groove there was a localised cyst-like patch of oedema 1 cm in diameter in the submucosa. This could be felt more easily than seen (fig 2). The mucosa over it had split to expose the submucosa, but this was probably an artefact. Both the mucosa and the external surface of the gut were of normal colour, and there was no evidence of inflammation or inflammatory ulceration, but the vessels of the serosa in the region of the annular defect were just perceptibly congested. The mesentery appeared normal.

Histology—The ulcerated area resembled gastric mucosa (fig 3). Mr L W Progor, pathological curator of the Royal College of Surgeons, commented as follows: "The section shows undoubted gastric mucous membrane with simple ulceration. These patches of heterotopic gastric mucosa are usually associated with some congenital malformation, such as atresia, reduplication, Meckel's diverticulum, or enteric cyst. I have not yet seen one associated with congenital stricture, as in your case."

I am indebted to Dr E Wordley and Dr M R Thomas for their assistance in preparing this article.

PEMPHIGUS ACUTUS TREATED WITH ANTIBIOTICS

THERESA LAZAR
M B Birm, M R C P

MEDICAL REGISTRAR, QUEEN ELIZABETH HOSPITAL, BIRMINGHAM

THE distinction between different forms of pemphigus is not always clear cut. Pemphigus acutus, however, is generally regarded as a definite entity (Sutton and Sutton 1939, MacKenna 1945). It occurs mostly in people whose work involves handling animal products, although cases have followed vaccination (Howe 1903). It is probably an infection caught through some breach in continuity of the skin, since many patients give a history of a cut or infective lesion on the fingers. A diplococcus was isolated from the lesions by Demme (1886), Claessen (1893), and Bulloch (1895), but this has not satisfied Koch's postulates. More recently a virus aetiology has been suggested (Markoff and Knauer 1939). Pemphigus acutus resembles pemphigus vulgaris in many respects, but runs a more rapid course. It has a mortality of 50-70% (MacLeod 1933, MacKenna 1945). Hitherto no treatment has been satisfactory.

Since the advent of antibiotics penicillin has been tried in various forms of pemphigus without success (Kolmer 1947, Florey et al 1949, Spink and Hall 1945), but I have been unable to find any specific reference to its use in pemphigus acutus.

Recent encouraging reports by Philip (1949), Bottley (1950), and Whittle (1950) on the use of Aureomycin

in pemphigus vulgaris have prompted the trial of this drug in the case described here

CASE RECORD

A man, aged 45, was admitted to the Queen Elizabeth Hospital under Prof. K. D. Wilkinson on Jan. 24, 1950. He was employed in driving a butcher's lorry and handling hides and skins. In early December 1949, a whitlow appeared on his left forefinger and persisted until admission. Otherwise he was well until Jan. 16, when he developed cough, with cough, malaise and "pimples" on his face. In the next two days blisters appeared all over his body. Later, his eyes began to discharge, and his throat became sore and his voice husky.

On admission the patient was very ill with temperature 100°F and pulse rate 116 per min. He had extreme foetor of the breath and body. He was hoarse and had a harsh cough, with large amounts of bloodstained sputum containing brownish yellow sloughs. The skin of the trunk, limbs and genitalia was covered with bullae. The fresh bullae were single blisters 1-2.5 cm in diameter on intact skin. The older ones were confluent, broken, discharging and surrounded by erythematous areas. The lesion was worst in the groins and axillae, where the whole epidermis seemed to be sloughing. On the scalp there were numerous firm dark scabs, and on the face a few small scabs. The conjunctivae were inflamed and discharging mucopus, the eyelids were ulcerated and covered with scabs. The mouth was difficult to examine because of trismus but several large bullae with irregular margins were seen on the mucosa, particularly on the under surface of the tongue. There was a purulent discharge from the glans penis. Fig. 1 shows the patient's appearance on admission. In the chest there were scanty clinical signs of bronchitis but radiography showed slight emphysema only. No abnormality was found in the heart, abdomen, or central nervous system.

Investigations—The urine was normal. The red-cell count and hemoglobin were normal, the white-cell count was 10,600 per c.mm. (polymorphs 62%). A swab from a fresh bulla showed no pus cells or organisms in the smear and no growth on culture. No significant organisms were grown from the discharge from the glans. Sputum culture yielded *Staph. pyogenes* which was insensitive to 0.2 unit but sensitive to 0.8 unit of penicillin per c.cm. Wassermann reaction and Kahn test were negative.

Treatment and Progress—A course of penicillin 50,000 units intramuscularly three hourly was started on Jan. 24, the day of admission. After three days of this the patient's condition was unchanged. Aureomycin was given from Jan. 26 in doses of 0.5 g six hourly by mouth. Twenty-four hours later the patient's general condition appeared very much better, the discharge from his eyes was less and the temperature lower (fig. 2). Only two small new lesions appeared after the start of aureomycin treatment the last one on Jan. 30, by which date there was no foetor and the skin of the face and eyelids was normal. By Feb. 6 the mouth and conjunctivae

Fig. 2—Temperature and treatment chart

were practically clear, the voice was much less hoarse, there was only a slight cough, with scanty white sputum. Most of the skin lesions had dried and left scabs, flexures and over the pressure points, however, removed bullae left large denuded areas discharging pus and fever. These were thought to explain the renewed and persistent fever. A culture from one of these areas yielded a *Staph. pyogenes* with a low sensitivity to aureomycin (bacteriostatic concentration 50 µg per ml), and sensitive to streptomycin 10 µg per ml. This finding led to the institution from Feb. 11 onwards of intramuscular streptomycin 0.5 g six hourly and the local application of streptomycin cream. On this treatment the discharge cleared, the skin was completely healed on Feb. 21, the cough with sputum remained, but the patient had had this for years. He was discharged on March 6.

DISCUSSION

The diagnosis of pemphigus acutus in this case is in doubt. The condition bears some resemblance to Stevens-Johnson syndrome but can be distinguished by the intense foetor of the whole body, the large blisters arising on intact skin and involving the scalp, the absence of the erythematous skin lesions, metrorrhagia in the mouth, and swelling, ulceration, and bleeding of the lips that are characteristic of Stevens-Johnson syndrome.

It is probable that antibiotic therapy may have influenced the course of the illness. But did the drugs act only on the secondary infection, or did both of them affect the disease itself? Streptomycin was started long after the last signs of active pemphigus had disappeared, and it can therefore only have influenced the secondary infection.

Pemphigus acutus did not have any noticeable improvement when given alone, and from a scientific point of view it is unfortunate that it was continued after the beginning of aureomycin treatment. However, the patient was so gravely ill, with a secondary infection, that it was not thought wise to withhold any drug that might help him. Although the aureomycin alone might have helped, being plentiful could be more generous doses of aureomycin the patient's general condition improved within twenty-four hours, and after eleven days the only signs left could be ascribed to secondary infection.

No claims can be based on this single case, but the

Fig. 1—Pemphigus acutus showing ulcerated eyelids, scabs on face and distribution of fresh and old bullae.

seems to justify a trial of aureomycin in other cases of this deadly disease

SUMMARY

A lorry driver, working with hides and skins, developed severe pemphigus acutus, characterised by an erythematous bullous eruption on the skin and mucosae, and extreme fever of the body. Penicillin alone was ineffective, but when aureomycin was given as well the patient improved rapidly.

I wish to thank Prof K. D. Wilkinson for advice and permission to publish the case, and Dr A. P. Peeney for the bacteriological investigations.

A THERAPEUTIC EXPERIMENT IN PEPTIC ULCER

J. B. STOLTE

M.D. Amsterdam

HEAD OF MEDICAL DEPARTMENT,
ST. ELISABETH HOSPITAL, TILBURG

In 1944 a new remedy for peptic ulcer was introduced in Switzerland under the name of 'Robuden'. This consists of watery extracts prepared from the wall of the stomach and intestines of newly killed animals and is given by mouth or by injection. The idea was not entirely new. Okada and Doi (1938) had previously experimented with a similar treatment, though their work has so far not been confirmed, and Sandweiss et al. (1939, 1941), and Ivy (1941) had tried enterogastrene, apparently without any lasting success. Robuden was found to be effective in experiments by Roulet (1945) on guinea-pigs and by Grandjean (1948) on rats, and clinical reports on its use in peptic ulcer, mostly favourable, have been published by Schmaszmann (1944), Keiser (1945), Pulver and Maier (1946), Neumann (1946, 1948), Kapp (1946), Hubacher (1946), Bellomo and Bologna (1947), Surkes (1947), Beer (1948), Bergamasco and Morelli (1948), Frémiesz and Roka (1948), Holy and Jelinek (1947), and Ackermann (1948).

In the last few years the treatment has acquired a considerable following in Switzerland and elsewhere, largely because of the good results reported in ambulant

patients—an attractive point in view of the shortage of hospital beds.

METHOD OF INVESTIGATION

A generous amount of robuden was supplied for trials by the Robapharm Laboratoriums A.G. There are two kinds of robuden injections, one for gastric and one for duodenal ulcer. Besides the injections, tablets are given which are the same for both kinds of ulcer. To decide on the respective effectiveness of the injections and the tablets we gave them separately (contrary to the manufacturers' directions) as follows.

On 10 consecutive days 1 ml. was given intramuscularly, followed by 5 doses of 1 ml. a day on alternate days. After the 15th injection a change was made to the tablets, of which the patient took one before meals three times a day for 4 weeks, then one twice a day for 2 weeks, and then one three times a day for the first 10 days of each of the next 3 months.

The patients were radiographed before the treatment started, after the 1st injection, and again 6 weeks or 3 months later. During the course of injections the symptoms were investigated, and the patients were weighed and, if necessary, examined physically. They were encouraged to keep at work and to eat normal meals. Smoking was not forbidden.

The total number of ampoules and tablets necessary for a complete course were put together in a numbered package. An equal number of placebo courses were put up, consisting of brown ampoules containing physiological saline solution and tablets made of talcum with milk sugar, coated like the robuden tablets. Only one person prepared the packages and knew the numbering. Neither the patient nor the person who gave the injections and tablets in the clinic knew whether the real or the placebo course was being given. The numbered packages were given out consecutively, and the numbering was decided by drawing lots. Patients with a duodenal ulcer were given injections for duodenal ulcer or placebo, those with gastric ulcer got injections for gastric ulcer or the placebo.

RESULTS

Robuden

The results are shown in the table. Of the patients with duodenal ulcer 93% were symptom free or greatly improved after the injections, and 70% after the tablets. For the patients with gastric ulcer the corresponding figures were 78% and 60%, and for duodenal and gastric groups together 86% and 66%.

Since no diet had been prescribed, and most patients had kept at work, these are undoubtedly good results, and they were confirmed by radiography. Of the 23 patients with gastric ulcer, 20 showed a considerably smaller niche or none at all after the course. In many cases the niche could not be demonstrated after 6 weeks. Usually the symptoms disappeared much earlier—several patients had none after the 3rd or 4th injection, and most were practically symptom free after the 8th injection.

Placebo

The results of the placebo courses (see table) were no less interesting. Of the patients with duodenal ulcer

RESULTS IN PEPTIC ULCER WITH INJECTIONS OR TABLETS OF ROBUDEN AND WITH CONTROL COURSES OF PLACEBOS

Type of ulcer	No of cases	Symptom free		Much improved		Poor result		Radiological changes in niche		
		Inj	Tab	Inj	Tab	Inj	Tab	Disappeared	Much smaller	Little changed
ROBUDEN										
Gastric	23	9	7	9	7	5	9	11	0	3
Duodenal	26	9	9	15	9	2	8			
Total	49	18	16	24	16	7	17	11	9	3
PLACEBOS										
Gastric	24	9	14	10	6	5	4	13	8	7
Duodenal	28	11	11	11	8	6	9			
Total	52	20	25	21	14	11	13	13	8	3

78% were symptom free or greatly improved after the saline injections, and 68% after the tablets. For the patients with gastric ulcer the corresponding figures were 78% and 83%, and for both groups together 78% and 75%. In contrast with the robuden course, the change from the injections to tablets was not accompanied by any notable reduction in the percentage of good results.

One of these patients, successfully treated with the placebo course, ordered genuine robuden tablets from a chemist for a relapse but had no benefit from them. Having detected, by biting them, a difference between the genuine tablets and those he had taken before, he asked for the placebo tablets. After taking these for three days he again became free from symptoms.

The effectiveness of the placebo course was confirmed by radiography in the patients with gastric ulcer. In 21 of the 24 patients the niche was much smaller or had entirely disappeared. The time for healing was exactly the same as with robuden therapy, and the symptoms disappeared in the same time.

COMMENT

The effectiveness of placebos in peptic ulcer is not unknown. Good results with placebo injections have

been described by Sandweiss (1936) and Martin (1947) and Gill (1947) obtained successful results in 20 patients treated exclusively with injections of distilled water.

The conclusion to be drawn is that any treatment exacerbations of peptic ulcer has a chance of success. In this respect robuden does not seem to be more effective than a placebo.

Reviews of Books

Biological Standardisation

(2nd ed) J H. BURN, professor of pharmacology in the University of Oxford, D J FINNEY, lecturer in the design and analysis of scientific experiment in the University of Oxford, L G GOODWIN, member of the staff of the Wellcome Laboratories of Tropical Medicine London Oxford University Press 1950 Pp 440 35s

This book is really the second edition of that written under the same title by Professor Burn alone some twelve years ago. The statistical analysis of results has been fully treated by Dr Finney, and the part on chemotherapy has been dealt with by Mr Goodwin.

Emphasis is laid throughout on the absolute necessity of having standard preparations which are tested simultaneously with the substance being assayed and which, being available to all laboratories, make it reasonably certain that a result obtained in one laboratory will, within the limits of experimental error, be equal to that obtained in another. There are now 39 International Standards for assaying the potency of preparations of different biological activities. It is a pity that no mention could be made of the new International Standard for vitamin D (crystalline vitamin D₂) which was adopted presumably between the writing of the chapter on vitamin D and the actual publication of the book. Nor is any mention made of the pioneer work of the British Standards Institution with a preparation of crystalline vitamin D₂, or of Kon's work on the assay of vitamin D in cod liver oils intended for chick feeding. Headings and subheadings in the chapter on vitamin D, as in some other chapters, are at the first reading confusing. Many of the methods of assay are treated historically but it is not always made clear which is the most recently accepted method. In the statistical section, the historical method is useful for it affords grounds for instructive criticism of the early methods of design and analysis and also reasons for the adoption of new ones.

The book will be invaluable to all workers on biological assay. Others who wish to know something of what biological assay means, without themselves carrying out experiments, will find it understandable and interestingly written. It is not merely a laboratory handbook but also a valuable treatise.

Le rétrécissement mitral

R LUTEMBACHER Paris Masson. 1950 Pp 304 Fr 1400

This account of mitral stenosis is written from the French point of view, and the English speaking reader will find that this differs from his own in many important particulars. As a cause of the condition syphilis is

considered almost as important as rheumatic fever and, in those cases regarded as rheumatic, salicylate credited with the power to relieve myocarditis. There is now a movement here to establish high blood levels of salicylate in acute rheumatism, few would admit that—even when given intravenously over a long period as recommended—it can have so beneficent an effect on the myocardium as Lutembacher contends. An interesting description of the mechanism and closure of the mitral valve is given, and a good deal of attention is paid to apical systolic murmur, but the way in which the mitral diastolic murmur evolves receives relatively little attention, and the extra sound heard in diastole at the apex is made unnecessarily mysterious. The problem of mitral stenosis and pregnancy is only briefly described and the emphasis placed on relative rarities, as compared with the commonplace, may be illustrated by the fact that auricular tachycardia receives a page or two while auricular fibrillation is dismissed in three lines. There seems to be no mention of mercury diuresis in the treatment of congestive failure, while for acute pulmonary oedema the impression given is that morphine is of more or less the same value as infiltration of the stell ganglion.

The British cardiologist will find much that is unacceptable in this book, but at the same time much to reflect on with profit. Many case reports are included and there are excellent photographs of valve lesions.

Principles of Ophthalmology

THOMSON HENDERSON, M.D., senior surgeon, Nottingham and Midland Eye Infirmary London Hemsley Medical Books 1950 Pp 230 20s

FROM his researches into the structure of the mammalian globe and his clinical investigations of the human eye, Mr Henderson chooses three points at which he differs from current teaching—the angle of the anterior chamber, the mechanism of accommodation and the intraocular pressure. He gives reasons for believing that the aqueous humour has access to the suprachoroidal space and that by this means particular matter is absorbed from the anterior chamber. More important, he thinks, is that this gives the retina a choroid a cushion and thus prevents their being damaged by compression against the sclera. (He does not explain adequately why aqueous does not escape when the space is exposed at operation.) He disagrees with the view that in accommodation the choroid moves slightly forward, while he also regards the statement that the intraocular pressure is normally about 25 mm Hg as erroneous; he believes that the intraocular pressure like the intracranial, is about 10 mm.

The author has given a great deal of thought to these statements, which are challenging and of great interest.

They deserve to be read by ophthalmologists everywhere, and no doubt contain a deal of truth. But he could have made his points equally well without referring to the "incomprehensible inanity" encountered in textbooks. It may even be that some of his own statements are not free from such a charge.

The Springs of Conduct

Sr JOHN PARSONS, CBE, FRCS, FRs London
J & A. Churchill 1950 Pp 104 7s 6d

It is a privilege to overhear a great man. Sir John Parsons covers in this book a range of material from neurology and the phylogeny of the nervous system to anthropology and the philosophy of mind—matter for many dozens of books—and does so with clarity and insight. His masters are McDougall, Whitehead, Trotter, and above all Sherrington. The philosophy of mind has, with the passage of time, moved beyond these writers, but they have left their impress on it and bear frequent revisiting. The only blemish, to the reader, is in an occasional looseness of phrase—"the bird is a species which has produced many varieties," "abnormal psychosis," and the like—which is worrying but not a serious bar to comprehension.

Eye Surgery

(2nd ed.) H B STALLARD, MBE, MD Camb, FRCS,
surgeon, Moorfields Eye Hospital, eye surgeon, St
Bartholomew's Hospital Bristol John Wright & Sons
1950 Pp 683 52s 6d

THE first edition of this book, coming at the end of the late war, contained a disproportionate amount of military surgery, nearly a third of it being on this subject. The author has now corrected this lack of balance. Besides 212 new illustrations, there is much new text, including particulars of the latest methods of treating retinal glioma, in which he has had a particularly large experience, and of some new plastic operations. The revised volume is a detailed account of the operations in common ophthalmic use, lucidly described and for the most part well illustrated. Possibly in places it is a shade fussy. Some surgeons may not like to be told to tie the surgeon's knots where stability is required, or the precise amount of procaine injected for a particular purpose. Perhaps the operation of advancement of the external rectus almost to the limbus should no longer find a place in such a book, and some pictures of enucleation of the eye would be a useful addition. But this is an outstanding work.

Syphilis Its Course and Management

EVAN W THOMAS, M.D., professor of clinical medicine,
New York University College of Medicine New York
and London Macmillan 1949 Pp 317 42s

Dr Thomas is one of the leading American authorities on syphilis and has played an important part in investigating the use of penicillin in its treatment. This book is not meant to be a complete textbook on the disease, its object is rather to present the life-history and to outline principles and methods of treatment.

The brief chapter on immunology is particularly clear and helpful. The section on serological tests and their interpretation and the clear exposition of therapeutic principles and up to date technical detail are all excellent. In conformity with American ideas and experience, penicillin is taken to be the drug of choice in all stages of syphilis, and the older remedies receive no more than summary mention. Dr Thomas is never content to rest upon the statements of others but gives facts and figures from the large and well studied material of the Bellevue Hospital.

Having disclaimed any intention of writing a full clinical description of the various stages of the disease it is perhaps a pity that the author attempted to describe them for this aspect of the subject is dealt with so sketchily as to be possibly misleading. Some brief excursions into pathology are equally unhappy. For instance the suggestion that gummatous ulcers of the skin usually arise from gummata which commence in the skin itself is inaccurate and liable to be confusing, and, in this country at least, it is not true that the commonest tertiary syphilitic lesion of the tongue is a localised gumma. In discussing the toxic effects of arsenical drugs Dr Thomas takes no account of the evidence that most cases of post-

arsphenamine jaundice are due to an infection, probably identical with the one that causes homologous serum jaundice.

For the expert and for the postgraduate student this will be a valuable supplement to standard works, but for the undergraduate it is unsuitable. The final chapter is a useful review of the public health aspects of syphilis by Dr Theodore Bauer, of the United States Public Health Service. The index is good and helpful, the bibliography is carefully compiled.

The Chicago Cook-County Health Survey

Conducted by the United States Public Health Service
Director K E MILLER, MD New York Columbia
University Press London Oxford University Press
1949 Pp 1317 120s

THIS is a comprehensive survey of facilities for maintaining and furthering the health of Chicago and its surrounding districts, with a full discussion of their merits and demerits and possible improvement. Undertaken by the Federal health service on the request of the mayor of Chicago and the president of the Board of Commissioners of Cook County, it is probably the most complete of its kind ever made anywhere. The report should be available in reference libraries to be used as a model in comparable inquiries. The results of similar surveys in this country would have been of great value in framing the National Health Service Act.

Urological Roentgenology (3rd ed London Henry Kimpton 1950 Pp 282 52s 6d).—Dr Miley Wasson's treatise with nearly 300 well produced radiographs remains supreme in its field.

Freeze-drying Drying by Sublimation (New York Reinhold Publishing Corporation 1949 Pp 280 40s).—This book, by Earl W Flosdorf, describes the development of freeze drying, and the physical data essential for the successful use of small scale and large scale apparatus, and gives details for the freeze drying of widely different products—from penicillin to carrots—with many valuable cautionary notes. A useful chapter deals with the use of acrylic plastics for the embedding of anatomical and pathological specimens.

Physiology of the Nervous System (3rd ed New York and London Oxford University Press 1949 Pp 067 75s).—It is six years since the second edition of Prof J F Fulton's *Neurophysiology* appeared. In that time the main direction of advance has been in our knowledge of the methods of activity of the cerebral hemispheres. It is particularly in this regard that the text of this edition has been revised and brought up to date. Such things as the suppressor areas of the cerebral cortex, the autonomic responses to stimulation of the orbital surface of the frontal lobes, and details of localisation of functions in the cerebellar hemispheres are all new and are all described here. Chapters such as those on the thalamus, the temporal lobes, and the precentral motor cortex also provide topical summaries which will be helpful to the busy reader who has difficulty in keeping abreast with rapidly changing views. Professor Fulton's bibliography runs into 80 pages, but it is critically compiled. Most doctors particularly concerned with the activity of the nervous system have used this readable and well presented book, and will continue to do so.

Combined Textbook of Obstetrics and Gynaecology (5th ed Edinburgh E & S Livingstone 1950 Pp 1411 70s).—Edited by Prof Dugald Baird, this well known text book has been enlarged by the addition of new chapters dealing with stillbirth, infant mortality, and the psychological factors in obstetrics and gynaecology, and more space has been given to the practical details of treatment. Emphasis is laid throughout on the preventive and physiological approach rather than on the operative side. In the section on obstetrics the breast pump is still advocated for the treatment of the engorged breast, and the diagnosis and treatment of the various forms of thrombosis are very scantily dealt with, without any description of anticoagulant therapy or the use of local anaesthesia. But such grounds for criticism are few and Professor Baird and his co authors must be congratulated on producing an excellent textbook which will not only be of great value in training medical students but will help the doctor to obtain a broader outlook in the field of obstetrics and gynaecology. The production, too, is excellent.

THE LANCET

LONDON SATURDAY, DEC 23, 1950

Priorities

Nobody can read the exultant reviews of medical progress over recent decades without asking "Where is all this leading?" With its scientific, economic, political, and philosophical implications, the question is so comprehensive that, rather than attempt an answer, most of us turn back to our immediate work. But within the larger question some narrower ones continually force themselves upon us. One of these is "Should our efforts be mainly directed to getting patients into hospital or to keeping them out of it?" Dr HUGH PAUL raises this again in his stimulating report as M.O.H. for Smethwick. He remarks that when a specialist proposes a scheme for improving work in his specialty—for instance, neurosurgery—the questions asked by the regional board are "What is the extent of the demand for this service?" and "What is the most economical way in which these demands can be met?" This, Dr PAUL says, is wrong. The first question should be "In what way can these demands be met without the provision of hospital beds? How can the number of patients suffering from neurosurgical conditions be reduced?" (The choice of neurosurgery for the example is not perhaps particularly happy, but the point is clear enough.) The reasons why hospital authorities do not approach the subject in this way are "firstly, they are not particularly interested in problems which they have never studied, and which they have never regarded as within their competence, and secondly, with one exception, no regional hospital board in this country has amongst its members a professional epidemiologist." The boards are also hampered in other ways by their make up. The business men who serve on them, and who previously served on the voluntary hospitals, are accustomed to judge the relative importance of things by financial criteria and now find their standards inapplicable. The hospital is not run for profit, and such a man may have no other values to take the place of the financial ones.

"Unlike the local authority member, he is not an expert in social values, and consequently can only interpret hospital efficiency in terms of the cost and size of equipment, the extent of the chromium and marble, and the appearance of the buildings. If the hospital has a larger X ray or a larger pathological department, or spends more on the kitchen equipment than another hospital, he is apt to assume that his hospital is better run than the others. This unfortunately does not follow."

Dr PAUL carries his argument further—perhaps too far—when he urges that the local authority representative, on the contrary, is "usually a man or woman who for many years has been accustomed to deal almost entirely in social values." His previous experience has led him to make such abstract comparisons as that between, for example, a new picture in an art gallery and the redecoration of the law courts, or a new boiler at the sewage farm. It is, of course, true that local authorities are not

to decide such questions, but many would be ready to follow Dr PAUL in his conclusion that "it appears that the ideal board is one composed, if not entirely, of members from major localities." There are, after all, other alternatives. One of them is to be found in a better understanding throughout the hospital service, from the members of the hospital management committee to the part to be played by the hospital.

The trouble is surely not so much that a member of the hospital board is unduly influenced by the magnificence of modern apparatus as that we have inherited from the past a belief that a hospital is progressing if it is growing larger and larger more than a hundred years known medical knowledge and so far outstripped resources that, with a few exceptions, not much in the public eye, progress has been made only by the extent to which the hospital service grows in its effort to catch up. Any of the older literature would prove this. What was true of individual hospitals has come to be held to be true of most hospitals, and now by a loose transfer of ideas to the hospital service as a whole. We have not even developed the data which would enable us to compare, over the years, the purposes to which hospital beds are put, though it is obvious that there have been radical changes of use. The result of "Halt" has been called at an arbitrary point. It is an Exchequer rather than by a rational inference within the health service as a whole.

A few minds have been troubled by the implications of such data as have been available. There are here and there in FLORENCE NIGHTINGALE'S work. By her study of statistics she drove home the lessons of the Crimean hospitals, and passed on to the *ventable* mortality in the Army at home and work for the health of the British soldier. Dr DAWSON, though caught up in the tide of the knowledge of progress at the London Hospital, later became convinced of the urgency of pairing the curative with the preventive services, and of not regarding voluntary hospitals as in any sense an exception to this principle. The theme ran through the Dawson report of 1927, but it remained a generalisation. Nobody was able to see how it could be brought down to earth and made a reality. That the hospital should itself be in positive health?—that there should be a clinic for the "healthy" as well as for the "sick"?—there was something unconvincing in such suggestions, however well intentioned. Was the medical education of the health to be brought in and given a seat on the hospital board? Sometimes that was tried, though it usually proved useful, it led to no change of outlook on the part of the hospital. The hospitals did not start handing over money for hospital services however demonstrable the need.

That is in fact where we stand today. As a result of administrative convenience the health services have had to be parcelled out under the National Health Service Act into parts I, II and III, but, in spite of a great deal of new machinery has been created, has not been established that the Minister, in allocating total resources, should be guided by a professional body backed with the necessary data. The problems between various parts of the service are still

by pressure from the different quarters, though the pressure is filtered by the Minister's staff of professional advisers. Is it not ultimately desirable that these top priorities should be discussed publicly, well in advance of the date when they must come into operation, by some such body as the Central Health Services Council? And that this body should be given a real opportunity of assessing, 'if not the amounts, at any rate the proportions in which the whole sum should be distributed? The change of principle involved in admitting such a body to participation in financial discussions would be so great as to make it unreasonable to press for more than the opportunity to discuss and to recommend at any rate for some years to come the Minister would have to retain the ultimate responsibility. But the very preparation of the data for such consideration would at once involve the Ministry in a range of most desirable inquiries into the relative claims of this and that on the public purse.

We must add that in all such thinking and reasoning there lurks a danger. From discussing the relative claims of this or that form of curative or preventive medicine it is but a short step to talking in terms of value to the community and thence to a crude utilitarianism which will prefer the interests of the workers to those of the aged, and the useful to the apparently useless. Even PLATO argued himself into this perverse position. As POPPER² has reminded us, PLATO was led to interpret medicine as a form of politics "the physician has no right to treat a man who cannot carry out his ordinary duties, for such a man is useless to himself and the State." The advocates of preventive medicine sometimes lapse into this risky doctrine, which is anathema to the doctor in the hospital as it is in the home. In a later section of his report Dr PAUL, like so many of us, begins to sail near the wind when he writes that it could "scarcely be denied that looking at the matter coldly, it is a business proposition to keep the people healthy rather than to allow them to become ill and then endeavour to cure them by the spectacular activity of a glamorous profession." It is surely a matter of some urgency that the danger-point at which good sense passes over into something very different should be more precisely defined. Perhaps those who are going to be our advisers on these matters should be required to include in their curriculum some knowledge of the Benthamite philosophy, and of the deep distrust of it felt by philosophers today, so that they may see clearly to what lengths they might easily be led.

The Last Disability

It would be inconvenient if our tastes remained unchanged through life. In *Vice Versa* the mature man, turned boy again, quails before a slab of suet pudding, and who, in his fifties, lightly rises to go rowing on an icy river before breakfast? But if life breaks us in kindly, in the main, to the waning of our early powers, there must always be cases where some special loss is hard to bear. Those who have led an active life are often much oppressed by the limitations of the ageing body. Our contributor writing on the disabilities of old age (p. 872) chafes

at his enforced inactivity, and must fight the restlessness it breeds in him. What, he asks, should, for the old, take the place of physical recreation? Women feel the force of this question less than men, for their "activity" is usually of a different order. Where an elderly man may still be playing such games as golf and bowls, or may enjoy walking or climbing in the open until late in life, an elderly woman is usually active about the house, and she can carry on with familiar household chores long after the man has been obliged to restrict his outdoor pursuits. Moreover, women are accustomed to using their hand muscles as freely as their limb muscles, and when walking becomes difficult they take cheerfully to hand-work as a substitute for leg work. A ward for old women is nearly always a more active and lively place than a ward for old men, because all the women are commonly engaged in making something, especially if they are encouraged by the nurse. It is much harder to get old men to value minor handicrafts. Yet, after all, physical recreation is very largely an opportunity to use muscles skilfully, to compete, and perhaps to excel. When the great muscles begin to fail, the small muscles can give the same satisfactions on a miniature scale.

Dr HOWARD COLLIER and Miss EVELYN STURGE, who have given some thought to the problem of growing old, suggest in a recent pamphlet¹ that old people are "the guests of the next generation," and like other guests they themselves help to determine the kind of welcome they receive. They can still do much for others, not only by such small services as are in their compass, but by their contented silence, their refreshing memories, their easy company. It is the part of age, these writers suggest, to withdraw into the background, but to do it in a way that makes nobody feel guilty. The old can keep up their interests by reading, and should be ready to talk on what they have read, little perhaps but well. An informed old person can, they think, sometimes waken an interest in poetry or biography in a younger member of the family. Since personal possessions become more of a burden with age, old people should gradually get rid of their belongings, keeping only those they specially prize. Writing from a religious standpoint, Dr COLLIER and Miss STURGE add much to mitigate the fear not only of death but of war and other disasters.

This pamphlet is addressed chiefly to people of some education, who may expect to grow old in their own homes, or the homes of their children or relatives. Their physical needs will be well looked after. In the community, however, we have many solitary old people of small means who in the past inevitably gravitated to the chronic wards of institutions, and still do so in areas where the care of the old is not yet fully organised. Most such old people dread falling sick because removal to hospital may mean final and complete loss of their homes, and for the same reason hospitals are loth to accept them, for an old person with no home to go to must be allowed to occupy a bed till he dies. But then as Sir ANDREW DAVIDSON lately put it,² a hospital is the last line of

1 *The Glory of Growing Old*. Friends Bookshop, Euston Road, London, N.W.1. Pp. 27. 6d.

2 Address by Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland, at the opening of an old people's home at Balmagask, Aberdeen, on Dec. 6.

efence Many, given some necessary help, can live in and keep well in their own homes, others do well in hostels or homes for old people. Some can go into hospital for treatment of an acute illness or a chronic disability and return to their homes able to carry on again, provided they can be helped with their housework, shopping, and cooking. Moreover, these kinds of help are less costly than hospital care. Sir ANDREW quoted the estimate of a medical officer of health that the total cost of caring for an elderly person in his or her home—including old-age pension, national assistance, and local authority services such as home help, district nurse, and health visitor—amounts to only about £98 yearly, or under £2 a week. A more elaborate scheme, including meals on wheels, a laundry service for those who specially need it, and the services of a chiropodist, would work out at £123 a year or nearly £2 10s a week. Care in a hostel costs £3 10s a week, and care in hospital anything from £8 a week upwards. He made it clear that the chief need of old people is not increased medical care—something like half of them, as surveys show, do not see a doctor from one year's end to the next, only about a fifth of them need frequent medical attention, though about the same proportion require regular visits from the district nurse. What they chiefly need is help with the heavier household jobs, relief from queueing, a cooked meal now and then, help with letter-writing, or simply a little company. Voluntary visitors who call on old people once a week can be very welcome, especially to those who cannot get about easily, but the more active old people of sociable disposition get great pleasure from old people's clubs. Sir ANDREW said that of every 100 people of pensionable age something like 25 need help of some kind. In any case some 95% of old people, he thinks, can get along in their own homes if those who need it are helped, and this is "a wide field of endeavour for local authorities and voluntary bodies working in close harmony."

It is appropriate perhaps that old age should be the subject of the last essay in our "Disabilities" series, though it is debatable whether old age as such should be regarded as a disability at all. The old today are many and increasing, and it becomes the task of the rest of us not only to treat and ease the disabilities of age, but also to give the old the chance to contribute their share to our common life. Like all the others who have written in this series, the writer of this last article makes it clear that a disability is something a man or woman carries—it is no more a part of him than his overcoat, and it has nothing to do with the capacities of the human spirit except to evoke them.

Gastric Biopsy in the Pernicious-anæmia Syndrome

ATROPHIC gastric mucosa in pernicious anæmia was described eighty years ago by SAMUEL FENWICK, but, because post-mortem changes set in so soon, histological studies have seldom been satisfactory. MAGNUS and UNGLEY¹ did obtain proper tissue, by adopting extraordinary measures, but these could not be repeated often, and nowadays necropsies on patients with pernicious anæmia in relapse are rare.

MAGNUS and UNGLEY found that in the fundus and body of the stomach the normal mucosa was replaced by an intestinal type of mucosa with relatively shallow glands, the pyloric portion of the stomach was relatively normal. Their findings were confirmed by COX,² who pointed out that the changes were unlike those of chronic gastritis, and also that the gastric changes persisted however long the disease had been present.

The idea of obtaining specimens of stomach during life came with the development of gastroscopes, and operating gastroscopes fitted with biopsy forceps have been described. The use of such instruments requires much skill by the operator and causes no little discomfort to the patient. Last year an Australian group³ described a flexible gastric-biopsy tube that was small, could be passed easily and quickly, and produced a fragment of gastric mucosa large enough for reasonable histological sections to be prepared. The method had the disadvantage that, without radiological control, it had to be used blind. With this instrument nearly 500 biopsies have now been performed, and in only 5 was there bleeding afterwards sufficient to cause hæmatemesis or melæna. Among the 33 cases of pernicious anæmia in this series they found⁴ much the same state of affairs as had their predecessors. The gastric mucosa is atrophic and of less than half the average depth, the gastric glands are almost completely atrophied, and a special stain shows very few cells with pepsinogen granules. The intestinal metaplasia noted by MAGNUS⁵ is common but not constant. Some infiltration with lymphocytes is present but is never dense. In chronic gastritis, cellular infiltration of the mucosa is dense, and polymorphs and plasma cells are present as well as lymphocytes, moreover, intestinal metaplasia is rare and residual clumps of pepsinogen cells are common. Some other interesting results have been obtained. For instance, JACOBSON⁶ had stated that argentaffine cells were absent in the mucosa of patients with pernicious anæmia who had not had liver treatment, and he suggested⁷ that the granules seen in argentaffine cells in normal mucosa contained a pterin substance, and this observation became specially interesting when it was found that folic acid is a pterin substance. However, in the gastric biopsy specimens argentaffine cells could be easily demonstrated. Another important point was that the gastric atrophy seemed permanent, and even after many years of proper treatment it showed no change.

DORG and WOOD suggested that their gastric biopsy technique could be usefully applied to the kind of case that has become the bane of medical outpatient departments—this is the patient who is thought by his doctor to be "anæmic," and so, without any blood examination, is given some blunderbuss preparation containing ineffective doses of liver, folic acid, iron, and probably "vitamins." The patient does not respond as expected, so he is sent to hospital for diagnosis, by then the blood picture will not be typical, and the bone marrow will be difficult to interpret. A gastric biopsy revealing typical atrophy

by pressure from the different quarters, though the pressure is filtered by the Minister's staff of professional advisers. Is it not ultimately desirable that these top priorities should be discussed publicly, well in advance of the date when they must come into operation, by some such body as the Central Health Services Council? And that this body should be given a real opportunity of assessing, 'if not the amounts, at any rate the proportions in which the whole sum should be distributed? The change of principle involved in admitting such a body to participation in financial discussions would be so great as to make it unreasonable to press for more than the opportunity to discuss and to recommend at any rate for some years to come the Minister would have to retain the ultimate responsibility. But the very preparation of the data for such consideration would at once involve the Ministry in a range of most desirable inquiries into the relative claims of this and that on the public purse.

We must add that in all such thinking and reasoning there lurks a danger. From discussing the relative claims of this or that form of curative or preventive medicine it is but a short step to talking in terms of value to the community and thence to a crude utilitarianism which will prefer the interests of the workers to those of the aged, and the useful to the apparently useless. Even PLATO argued himself into this perverse position. As POPPER² has reminded us, PLATO was led to interpret medicine as a form of politics: "the physician has no right to treat a man who cannot carry out his ordinary duties, for such a man is useless to himself and the State." The advocates of preventive medicine sometimes lapse into this risky doctrine, which is anathema to the doctor in the hospital as it is in the home. in damp refuse. In the country it is harder, of course, to abolish breeding places, but with common sense and residual insecticides the problem is not insoluble. Those asked for advice on the subject can do no better than recommend a recent publication designed for the layman by the Ross Institute¹, this emphasises general principles of fly destruction, avoiding that excessive dogmatism which leads to disappointment.

We should all, no doubt, be keener on destroying flies if there were stronger evidence that they play an important part in the spread of disease. During campaigns in the Near East it has been noted several times that the number of hospital admissions for dysentery varied with the active fly population, and the point of this observation has been sharpened by the finding of species of *Shigella* (and of *Salmonella typhi* and the virus of poliomyelitis) on the feet of flies which have had access to human excreta. But we need to know more. For example, how many flies abandon the delights of the latrine for the joys of the kitchen, and can one fly carry enough organisms to infect one man? (Tubercle bacilli occur in the mouths of those with phthisis, glasses on licensed premises often receive no cleaning beyond "a lick and a promise". Does the tosspot hence run a much greater risk of infection than the abstainer?) And the danger of an argument based on coincidence is that it may be no more than coincidence, it is possible that the seasons of maximum fly population in the Near East were also those of foulest climate, fungal diseases of the skin, and universal longing to be elsewhere. Hope's² classical paper on the relation of temperature, flies, and infantile enteritis is convicting evidence only up to a point, for three successive years the disease became prevalent as soon as the fly population reached a certain level, but that this did not occur in the fourth year suggests that the relation was not a simple one of cause and effect.

All these subjects might be re-examined with the advantages of newer techniques, and meanwhile we shall do no harm if we regard musca as an unwelcome intruder in our own, or any other, kitchen. Public health has many unknown heroes on its roll of honour, and few have had less credit than that ingenious lady—the sex need not be doubted—who sewed some beads round a square of muslin and taught mothers how to keep flies out of baby's milk.

DRUGS FOR DYSENTERY

In 50–80% of the cases of bacillary dysentery investigated by the Public Health Laboratory Service in the last few years the organism isolated was *Shigella sonnei*. Glover's studies³ of the notifications in England and Wales have shown that epidemic waves of dysentery, probably of the Sonne type, mainly occur in the autumn and late winter or early spring, and that children under 5 years account for about a third of the dysentery notifications in males but only about a fifth in females. Why little boys are much more susceptible than little girls, and what determines the seasonal incidence, is unknown. The human alimentary tract is believed to be the chief, if not the only, reservoir of infection, and it is particularly difficult to prevent and control the spread of the Sonne bacillus among children attending day nurseries or nursery schools or among the inmates of children's residential institutions.

Since 1945, despite the fluctuating incidence, mortality from bacillary dysentery has steadily declined. This association of fluctuating incidence with declining mortality is found also with scarlet fever, and here it has been attributed to the increasing use of the sulphonamides. A similar explanation may also account

for the falling mortality from bacillary dysentery, against which sulphonamides have been used since 1940. At first the relatively poorly absorbed sulphaguanidine and succinylsulphathiazole were regarded as the drugs of choice, but in 1946 Hardy⁴ finally proved that the most readily absorbed sulphonamides, such as sulphadiazine, are the most effective against *Shigella* infections. Usually treatment of Sonne dysentery with such sulphonamides is extremely successful, unfortunately, however, application of sulphonamide therapy is not always straightforward. Thus in some infants and children who have had severe or long continued diarrhoea before the cause is recognised as *Shigella* infection, the administration of any sulphonamide may be dangerous until dehydration has been corrected, and thus the start of chemotherapy may be delayed for as much as thirty-six hours. Then occasionally severe acquired hypersensitivity or specific idiosyncrasy to sulphonamides may bar their use. Another difficulty, often mentioned but at present perhaps more theoretical than real, is that in the presence of resistant strains sulphonamide therapy may either fail to cure or result in relapse or a chronic carrier state.

It now seems that, where sulphonamides cannot be used, chloramphenicol is likely to be the most useful alternative. Mazursky,⁵ for instance, obtained excellent results with chloramphenicol by mouth in 3 children with Sonne infection, and in a much larger study of 35 cases, 33 of which were due to the Sonne bacillus, Ross and his associates⁶ achieved results with this drug that were as good as, or better than, those in controls treated either with sulphadiazine or with streptomycin.

FINGER-PRINTS IN DIAGNOSIS

THE patterns of the papillary ridges on the distal phalanges are formed in utero and their constancy throughout life has been proved beyond question. The prints that form the basis of the various identification systems adopted by the police of different countries—the Bertillon system still used in France, the Henry system which has largely superseded it elsewhere, and the one founded by Sir Francis Galton⁷ from which our own system has evolved—are obtained by inking these ridges. Lately, however, Chief Superintendent Cherrill,⁸ of Scotland Yard, has drawn attention in *Nature* to the creases which appear

in some finger prints as white lines crossing the papillary ridges (see figure). These creases are not of occupational origin and must be distinguished from transitory wrinkles and cracks caused by immersion or local irritants, and from scars of cuts made with a sharp knife, which they closely resemble. The white lines are ignored in police classification

cations of finger prints because they vary in size and number, sometimes within a day or two, they have been found in babies and may be very well marked in old age, and studies on the cadaver suggest that new ones may appear after death. About 1 in every 10 apparently normal people aged 16–75 have white lines, mainly on the middle, ring, and little fingers of the left hand and sometimes only on the left ring and middle fingers. The lines are commonest over the distribution of the dorsal cutaneous branch of the ulnar nerve.

or intestinal metaplasia would be useful evidence in favour of pernicious anaemia, mucosa that showed the changes of chronic inflammation, or no abnormality at all, would be evidence against pernicious anaemia. In this issue the Australian team describe their application of this method, and of these arguments, to the diagnosis of the neurological part of the pernicious anaemia syndrome. Here, it must be confessed, they are less convincing. Clearly the problem in Australia is somewhat different. "In Australia," they say, "there are few conditions which so often escape diagnosis until an irrecoverable stage is reached." One cause of delay in diagnosis is "a reluctance to diagnose subacute combined degeneration of the cord unless there is a well defined picture of pernicious anaemia in the peripheral blood." Again, "cases simulating peripheral neuritis are usually treated uselessly with vitamin B₁₂ and progress until the diagnosis of subacute combined degeneration becomes obvious." These statements would not often apply in this country. The impression is strengthened by the records of the patients described, our feeling is that, sent to a clinic where such refinements as gastric biopsy were available, they would have been satisfactorily diagnosed and treated without recourse to gastric biopsy. This is not to say that a problem does not exist—it does. The problem patient is one, of suitable age, who complains of persistent paresthesiae in the distal parts of the limbs, and shows organic impairment of vibration and joint sense,

motor changes have not yet appeared, no anaemia is present, and the bone marrow is reported as normal, but achlorhydria is found. What would happen if gastric biopsies were done on such patients, and if those who had mucosal changes like those described in pernicious anaemia were treated with proper doses of liver or desiccated stomach? Would the paresthesiae disappear and would the syndrome be arrested? Dorr and his associates offer no evidence on this crucial point, they may have to wait awhile before producing it, because the patients must be watched for years rather than months.

It is well known that the patient with subacute combined degeneration of the cord whose outlook for recovery is worst is the one who is not anaemic. The reward for early diagnosis, if in fact treatment will prevent extension, is consequently very great. The difficulties of making a diagnosis that has to rest on the appreciation of mild, often mainly subjective, neurological changes, at an age when symptoms like dysaesthesiae may be due to several causes, are properly emphasised by the Australian workers. The value of gastric biopsy depends a good deal on what proportion of such cases prove to have mucosal changes of the pernicious-anaemia type, this figure also remains to be determined. Gastric biopsy, in the hands of its inventors, has proved a useful research tool. As a diagnostic technique it is still in the chrysalis stage, and its emergence depends on the answers to questions like those we have posed.

Annotations

THE COST OF ILLNESS IN HOSPITAL

We all know that hospital costs are rising, and that they put an increasing burden on the British taxpayer, but at least this burden is widely distributed among sick and healthy alike, whereas in other countries, if the wage earner of limited means, whether by mischance or lack of foresight, fails to cover himself fully by voluntary insurance, even a short illness in the family may spell financial disaster. The investigation in hospital of a pyrexia of unknown origin can cost as much as £80, and when a patient with tuberculosis has a thoracoplasty his hospital costs may well amount to over £1000. As Sir Lionel Whitby remarked when he quoted these figures¹ in his inaugural address at King's College Hospital, these economic considerations were a potent factor in hastening the institution of a national medical service.

An American team² has been studying the cost of a hospital illness to "non indigent persons" admitted in one fortnight to 13 hospitals in the District of Columbia. The average inclusive cost for the 1796 patients was \$285, or £100 at the present rate of exchange. About two thirds of the patients subscribed to voluntary insurance schemes which defrayed a varying proportion of the charges, the remainder, who included a high proportion of the lowest income group, could claim no such relief, and some of them had to add loss of earnings to their other troubles. It seems reasonable to conclude that "the cost of a single illness is often beyond the capacity of the family to meet," and the health insurance Bills now before Congress (summarised on p. 815 last week) should be viewed against this background.

Few people in this country today would dispute the inevitability of State help in paying the costs of illness, but it is often asked whether the State can now afford

to bear the whole expense of treatment in hospital. Reporting on a tour of Swedish hospitals arranged by the International Hospital Federation, Dodd³ expresses the view that "Sweden will be making a profound mistake if it follows the British National Health Service Act and charges nothing for hospital maintenance directly to the patient at the time of entering hospital. Whether the patient is allowed to insure privately or has to do it through the State is not so important as the principle involved—namely, that patients in hospital should not receive entirely free board and lodging which the patient ill at home has to pay for out of his own resources." Rees⁴ remarks that, "though the N.H.S. has been widely advertised as a free health service, it has never been advertised as a free hotel service," and he advocates a charge for board of £1 a week for those hospital inpatients who can afford it. Sir Ronald Davison, who was the first to publish proposals on these lines,⁵ suggested a standard charge of £2 a week for accommodation, food, and service, and estimated that 50% of patients might be expected to pay this in full while another 25% might pay half. He calculated that in May, 1949, when he wrote, these charges would save some £26 million, which could more usefully be employed in the extension of medical facilities and staffs. Unpleasant though the reintroduction of a means test would be, the proposal has merits which have never yet, perhaps, been sufficiently considered.

HOUSE-FLIES

THOSE who have shared their dinner in the Near East with *Musca domestica* will not usually attach much importance to the half dozen specimens which rest on the kitchen ceiling at home. But the house fly is an offensive animal, and in towns at least, neighbourly behaviour demands that it should not be given suitable nurseries.

Glover's studies³ of the notifications in England and Wales have shown that epidemic waves of dysentery, probably of the Sonne type, mainly occur in the autumn and late winter or early spring, and that children under 5 years account for about a third of the dysentery notifications in males but only about a fifth in females. Why little boys are much more susceptible than little girls, and what determines the seasonal incidence, is unknown. The human alimentary tract is believed to be the chief, if not the only, reservoir of infection and it is particularly difficult to prevent and control the spread of the Sonne bacillus among children attending day nurseries or nursery schools or among the inmates of children's residential institutions.

Since 1945 despite the fluctuating incidence mortality from bacillary dysentery has steadily declined. This association of fluctuating incidence with declining mortality is found also with scarlet fever, and here it has been attributed to the increasing use of the sulphonamides. A similar explanation may also account

for the falling mortality from bacillary dysentery, against which sulphonamides have been used since 1940. At first the relatively poorly absorbed sulphaguanidine and succinylsulphathiazole were regarded as the drugs of choice, but in 1946 Hardy⁴ finally proved that the most readily absorbed sulphonamides, such as sulphadiazine, are the most effective against *Shigella* infections. Usually treatment of Sonne dysentery with such sulphonamides is extremely successful, unfortunately, however, application of sulphonamide therapy is not always straightforward. Thus in some infants and children who have had severe or long-continued diarrhoea before the cause is recognised as *Shigella* infection, the administration of any sulphonamide may be dangerous until dehydration has been corrected and thus the start of chemotherapy may be delayed for as much as thirty-six hours. Then occasionally severe acquired hypersensitivity or specific idiosyncrasy to sulphonamides may bar their use. Another difficulty often mentioned but at present perhaps more theoretical than real, is that in the presence of resistant strains sulphonamide therapy may either fail to cure or result in relapse or a chronic carrier state.

It now seems that, where sulphonamides cannot be used, chloramphenicol is likely to be the most useful alternative. Mazursky,⁵ for instance, obtained excellent results with chloramphenicol by mouth in 3 children with Sonne infection, and in a much larger study of 35 cases, 33 of which were due to the Sonne bacillus, Ross and his associates⁶ achieved results with this drug that were as good as, or better than those in controls treated either with sulphadiazine or with streptomycin.

FINGER-PRINTS IN DIAGNOSIS

The patterns of the papillary ridges on the distal phalanges are formed in utero and their constancy throughout life has been proved beyond question. The prints that form the basis of the various identification systems adopted by the police of different countries—the Bertillon system still used in France, the Henry system which has largely superseded it elsewhere, and the one founded by Sir Francis Galton⁷ from which our own system has evolved—are obtained by inking these ridges. Lately, however, Chief Superintendent Cherrill,⁸ of Scotland Yard, has drawn attention in *Nature* to the creases which appear

in some finger prints as white lines crossing the papillary ridges (see figure). These creases are not of occupational origin and must be distinguished from transitory wrinkles and cracks caused by immersion or local irritants and from scars of cuts made with a sharp knife which they closely resemble. The white lines are ignored in police classifications of finger prints because they vary in size and number, sometimes within a day or two, they have been found in babies and may be very well marked in old age, and studies on the cadaver suggest that new ones may appear after death. About 1 in every 10 apparently normal people aged 16–75 have white lines, mainly on the middle, ring and little fingers of the left hand and sometimes only on the left ring and middle fingers. The lines are commonest over the distribution of the dorsal cutaneous branch of the ulnar nerve.

8 Cherrill F. R. Nature Lond. 1950 166 581.

Cherrill suggests that finger prints in general, and the whitelines in particular, might be valuable aids to medical diagnosis. Unfortunately, however, the illustrations he gives are not very convincing. They include prints in Darier's disease (keratosis follicularis) and poliomyelitis, and from a doctor with lesions caused by radium. In the girl with poliomyelitis prints from the unparalysed hand were normal, but those from the paralysed hand showed abnormal distension of the mouths of the sweat glands (the minute white dots running in single file along the ridges) and atrophy of the corneous and Malpighian layers of the epidermis, so that in places two fine ridges appeared where a normal print has a single ridge. Such double ridges are a recognised feature of prints taken some time after the epidermis of the finger has been removed, they may be produced by the double row of papillae normally present in the dermis immediately below each epidermal ridge. Cherrill also includes the prints of a patient with spinal tuberculosis to show how, as the disease progresses, the papillary ridges atrophy to knife edge dimensions. When Braasch and Nickson³ took wax impressions of the finger tips in radiologists and a control group they found abnormalities of the papillary ridges, ranging from localised flattening to general atrophy or proliferation, in 48% of the radiologists and 18% of the controls. The incidence rose with years of exposure to reach 100% in the radiologists who had practised for over thirty five years. Degenerative changes in the ridge patterns and nail beds seem to be a usual finding in very old people. An example of atrophy of the papillary ridges presumably resulting from a congenital defect of the skin is reported from South Africa by Dr Findlay and Mr Barnes in this issue (p. 846). Their patient, a Bantu girl of 13, is the first recorded case of congenital porphyria in an African. In addition to widely distributed cutaneous bullae, crusting, and scar ring, mainly on the exposed parts, the girl had stiff claw like fingers, with tightly drawn skin, the pulp of her terminal phalanges was sclerotic and translucent, and the paronychia tissues had retracted so that the nails overlapped the finger tips at the sides. The right thumb and index finger were most severely affected, and since the child was right handed the sclerosis seems likely to have been precipitated by everyday trauma rather than sunlight.

To experienced observers like Chief Superintendent Cherrill the terminal phalanges no doubt offer useful clues to their owner's state of health as well as his identity, and a dermatologist in search of a thesis subject might do worse than choose "The Finger-tips in Disease, with special reference to the Medical Applications of Finger prints."

MEDICAL EXAMINATIONS IN WALES

Greenwood and Lewis Fanning,⁴ writing on the statistics of medical graduation, noted a surprising lack of published material—surprising because, as they pointed out, "the medical profession has been longer and more sedulously examined than others." Among their statistical predecessors in this field they were able to claim only the London Hospital surgeon, Walter Rivington, who published in 1879 and 1888 two large and partly polemical books on the degree examinations of the University of London. Earlier records may have existed, but Greenwood and Lewis Fanning cite Munk for the allegation, made "with proper indignation, that the loss of certain eighteenth century records is believed to be due to the desire of an officer of the College [of Physicians] to conceal the fact that he had once been ploughed."

The twentieth century statistician has an altogether easier time of it, and Lewis-Fanning⁵ has made good use

of facilities afforded him by the Welsh National School of Medicine for a study of examination results over a ten year period. He had at his disposal records of all students admitted to one or other of the university colleges of Wales for preclinical training, during the years 1933-42. Altogether 470 of them proposed studying for the Welsh degree, and it is with these students that the report mainly deals. They were divided into three groups: those with total exemption from the preliminary subjects (physics, chemistry, and biology), those with partial exemption (one or two subjects), and those with none. These groups contained respectively 38, 92, and 340 students. For the men exemption in physics was slightly commoner than in biology (19% against 15%), while for the women a far higher proportion were exempted in biology (28%) than in physics (8%)—presumably a reflection of teaching differences in the schools. One purpose of the survey was to compare the three exemption groups in terms of their subsequent examination results. It had been held that those who received training in the preliminary subjects was completed within the university had a better foundation for later studies than those who had passed the first examination before admission to the university. The evidence, however, seems to be against this view. Thus none of the total exemption group dropped out through later examination failure, while of the partial exemption group 5% and of the no exemption group 24% were eliminated. If other causes of wastage, besides failing examinations, are taken into consideration the elimination rates become 13% for the total exemption, 14% for the partial exemption, and 32% for the no exemption.

Similar comparisons can be based on other criteria, such as average number of unsuccessful attempts at each examination, proportion of passes at each attempt, or time taken to obtain the degree, and each of these supports the same conclusion. Even when allowance is made for the fact that the exemption groups had fewer examinations to take, they still appear to have the advantage. One possible reason is that at schools the candidates for the Higher Certificate, which affords exemption, are usually selected for their ability. Moreover, Johnson⁶ has pointed out that in the London 1st M.B. the failure rate among external students is far higher than that normally found among internal students of the university, and this could well be taken to indicate a higher level of ability in those who pass externally. If this is also the case in Wales, the total-exemption group could be regarded as more highly selected than the others, and the difference in prognosis between the groups would reflect the stringency of the examinations they had passed rather than the quality of their training.

If all three groups are considered together, it appears that the over all wastage rate is about 27%—notably higher than the figure of 12½% which the Goodenough Committee were inclined to accept as representative, and probably a more realistic estimate.⁷ Some information was also available about qualifications other than the Welsh. Of all students enrolled in this ten year period 52% studied for the Welsh degree alone, 10% for both Welsh and London degrees, 23% for the Welsh degree and the Conjoint examination, and 4% for all three. The remaining 11% either attempted only London or Conjoint, or failed to sit any examination. Among those who set out to take a London degree the wastage rate was higher than it was among those who set out to take a Welsh degree, but these wastage rates do not enable one to compare the two examinations, since many who obtain a Welsh degree do not seek another.

We have to record that Sir LEONARD PARSONS, F.R.S., died in Birmingham last Sunday.

CORONARY DISEASE AND MODERN STRESS*

I McD G STEWART

M D Lond, M R C P

SENIOR MEDICAL REGISTRAR, BRISTOL ROYAL INFIRMARY,
TUTOR IN MEDICINE IN THE UNIVERSITY OF BRISTOL

THERE has been a vast increase in coronary disease during the present century. The malady strikes predominantly men in middle life. It is common to all modern States, yet in some thickly populated parts of the world it is unknown. The immunity enjoyed by members of primitive races disappears if they subject themselves, in exile, to the rigours of civilised life. Two main influences are brought to them by civilisation—unfamiliar mental stress, and increased richness of diet. The first of these is considered here.

THE MIND AND DISEASE

We are continually assured that the 20th century belongs to the Common Man. In medicine it is the Whole Man who has become the fashion. This is the age of the psychosomatic approach. An early question to be decided on first encountering a patient is: What sort of person is this? In the language of the initiate, assiduous efforts are now made to relate organic illness with basic personality type. It proves a considerable task, since personality not only creates its own endogenous stresses but also determines such factors as occupation, which further introduce the extraneous influences of environment.

In some diseases, however, the relation appears clear enough. Thus, few doctors could have much difficulty in agreeing with Avery Jones (1948) that sufferers from peptic ulceration tend to be "tense, possess unusual drive, and are over conscientious in their work. They worry unduly, but do not give way to their emotions." In fact, they belong to what Ogilvie (1949) describes as the "surgical registrar type," a category not so narrow, one ventures to think, as totally to exclude medical registrars.

A similar connection between disease and type of personality is sometimes claimed on grounds which appear less substantial. Wittkover (1938) studied 40 unselected cases of ulcerative colitis. According to him the illness was preceded by psychological abnormalities in 37 of them. He ascribed to these patients a fair selection of the traits of human temperament. In particular he decided, like Hardy (1945), that colitis tends to occur in a "mother's boy" sort of person, contrasting thus with the psychologically mature ulcer type. Paulley (1949) now suggests that the temperament of regional ileitis victims may be somewhere between the two. At this rate it appears that a precise mentality is shortly to be affixed to disorder in every foot of gut.

Inevitably there is also a "coronary type" personality. Most physicians have their own ideas of it. The psychiatrists are explicit. Describing the temperaments he found in a group of people who had suffered coronary infarction Arlow (1945), at a meeting in America, remarked that "what disturbed these patients most was to fail in the rôle of their deeper identification, and to fail under circumstances which convinced both the outer world and themselves that they were not as good as they thought." Fear of failure, he observed, was always liable to turn to aggression, "the kind of identification one sees in women." It was then associated with "sexual fear and identification with the male" accompanied by "a desire to oppose them in open competition."

* Extracted from the Carey Coombs prize essay, University of Bristol, for 1949.

The trouble with this kind of speculation is that it is too comprehensive. There is something for everybody. "I thought I recognised myself rather clearly" was Dock's comment after he had listened to these observations by Arlow. There remains always the fundamental question: How far does all this affect structure? "Do you gentlemen mean," inquired Boas quizzically at the same distinguished gathering, "that these mental mechanisms are the cause of arteriosclerosis?"

In truth the problem is not simple. Ogilvie (1949) accepts essential hypertension as "a new disease, and a stress disease—the price the millionaire pays for his directorships and the clerk for his failure." But when asked how stress can cause this effect he replies "I do not know, and if anyone does he has not told me." Any attempt to find a psychosomatic explanation for coronary atheroma and its syndromes must encounter much the same difficulty. Wits (1949) has pointed out that the rôle of the mind in the pathogenesis of organic illness is more difficult to assess than is popularly supposed, and that in those few maladies, such as thyrotoxicosis, in which its influence has been established the demonstration has been achieved only as a result of elaborate laboratory research, never (according to Wits) from the recesses of an armchair. And seldom, I suggest, from within the curtained closets of the psychiatrists. Nevertheless, there are recognisable today many associations between conditions of life and specific illness. Always there is the hope that study of such links may produce a clue to aetiology. That the stress of modern times may contribute to the causation of coronary disease is a possibility that merits such examination.

The genesis of mental stress must depend on the nature of the predicament that causes it in relation to the character of the person involved. Heredity is the main factor in the determination of character. Admittedly it is responsible for much else besides. At this stage let us consider in all its aspects heredity as it bears on the aetiology of coronary disease. Later there will be examined the forms of mental stress which may be evoked by modern conditions of life in persons whose native temperament renders them susceptible. Finally there will remain to be answered the fundamental question whether sufferers from coronary disease can be identified as the particular victims of these new mental stresses.

HEREDITY

Boyd (1934) includes coronary disease among those conditions which may result from inherited constitutional "weakness." Coombs (1926) and Hadfield (1927) took much the same view. Indeed the contention is scarcely in dispute. It receives general assent from clinicians. Cassidy (1946) considered that half his cases showed a family history of the illness, and Levine (1929) holds that heredity is of "considerable importance," adding "it is amazing how frequently one finds various members of the same family suffering from early vascular hypertension or coronary disease." Ryle (1948), too, accepted the fact that "genetic factors" probably play a part, "whether through physical or temperamental predispositions or both." Dock (1946) points out that there is a hereditary variation in the thickness of the coronary intima which follows the sex difference in the incidence of coronary disease.

Controlled statistics have been provided by Yater et al (1948) for myocardial infarctions in young American soldiers. They discovered a history of coronary or hypertensive disease in 41% of close relatives, a term which they define as including only father, mother, brother, and sister. This percentage they compared with a group of hospital amputation patients. Of these only 13% admitted a similar family history. Hypertension and coronary disorder are, of course, by no means invariably associated. Nevertheless there exists a close

relation between the two, particularly among women at all ages and in the older patients of both sexes. It is reasonable to conclude that heredity is an important factor in the pathogenesis of coronary affection. Further inquiry is thus suggested into the physical and mental components of diathesis.

The famous physicians of the recent past judged constitution to be of great significance. In assessing it they tended, perhaps, to rely more upon physical qualities than upon the temperament of their patients. Hurst, in the tradition of Addison, Bright, and Hodgkin, was wont to assume a whole chapter of information from the width of a costal angle. According to this school of thought coronary disease develops in the sthenic or Eustachian type of man. Osler (1910), however, already took account of temperament in maintaining that he could recognise his angina patients as they entered the room. He described in detail "a well set man from 45 to 55 years of age, with military bearing, iron grey, and florid complexion." He would be "robust and vigorous in mind and body, the keen and ambitious man, the indicator of whose engines is always set at 'Full Speed Ahead'." Levine's (1929) phraseology is much the same. "The typical patient is a well set person, somewhat overweight, physically strong with the appearance of good health and capable of vigorous physical effort." Many physicians today would agree with these impressions.

In Boston they deal with somatotypes. According to White and Ferrero (1949) they have been finding there that it is "the mesomorphic young male who is particularly prone to early coronary thrombosis," whereas the ectomorphic type is happily spared. Even in America, however, statistics scarcely keep pace with clinical impressions. Yater et al (1948) concluded that stature was irrelevant.

Investigation by many authorities has, in fact, revealed that the physical element in constitution, so far as it is perceptible to clinical examination, is not very helpful. Little more can be shown than the fact that obesity, particularly in men, predisposes somewhat to coronary atheroma. The hereditary variation in the thickness of the coronary intima may be of much greater importance.

Neither can there be any clear cut standard of "temperamental predisposition" to mental stress. The test of war proves that the resources of human nature are unpredictable. In time of peace a man's inherent temper guides him in his choice of employment. Any tension which his work may engender then plays back on his mind and personality. It is reasonable, therefore, before attempting to survey the problem of stress as a whole, to pass from the mental and physical sanctions exacted by heredity to those deriving from environment as presented by education, occupation, and class.

EDUCATION, OCCUPATION, AND CLASS

It is well established that not all members of the community are equally menaced by coronary disease. Doctors are wont to complain with reason that they are worse hit than any. Much has recently been written on the subject in America. It has been shown that the death rate among medical practitioners rises sharply, in comparison with the average, above the age of 45, this increase being largely due to cardiac maladies. Dublin et al (1947) give as 1.18 the mortality ratio expressing the death rate due to heart disease among doctors compared with that affecting the general male population of parallel age. Others go further. Dickinson and Walker (1948) echo Osler and many of their own contemporaries in declaring roundly that "heart disease is in reality an occupational hazard of the medical profession." The *Journal of the American Medical Association* (1944) blamed it for 1 death in 5 among American physicians.

During a clinical meeting in the same year Dock observed to his interested colleagues that coronary affection might well be worthy of their interest, since "a quarter of us in this room are going to die of it."

How does this proportion compare with that in other professions? Cassidy (1946) maintained that there was "an unquestionably heavier incidence of coronary disease in the non-hospital as opposed to the hospital population." Although they refer to a period which includes some of the years before the war of 1939-45, the figures provided by the Registrar General's last Decennial Supplement afford information of great interest. The adult population is divided into five successive classes on grounds of occupation and income, two factors which a few years ago bore a closer relation to each other than in these days, when the charwoman is so much better off than the ward sister, and the income of a prolific docker exceeds that of a celibate university tutor. Class 1 contains the professional workers, and the grades then proceed to class 5, which is made up of unskilled labourers. It is seen that the proportion of deaths from coronary disease is well above the average in the first two classes, and well below it in the last three. Even more remarkable is a comparison of occupational groups in which the figure 100 is taken to represent the average death rate from coronary disease for all males aged 20-65. The following significant figures are revealed:

Agricultural workers	32
Coalminers below ground	40
Banking and insurance officials	183
Anglican clergy	218
Physicians and surgeons	368

In the face of such evidence it is difficult to see how Master (1947) can justify his contention that "no occupation has any priority in this disease," even if it be true that "rich and poor, the labourer, the executive, the ordinary man at his desk are all possible victims." His view sharply exemplifies the dissent at the highest professional level that so often enlivens discussion of the aetiology of coronary heart disease.

Less attention has been paid to physical stress. Levine (1929) is "inclined to think that hard physical work is conducive to early disease of the coronary arteries." He declares himself to have been "impressed by the fact that athletes seem to succumb to vascular disease in surprisingly early years of adult life." It is generally believed, however, that great exertion never initiates damage to the heart. The effect of physical labour was further investigated in America by Phipps (1936), who showed that the prognosis after a thrombotic attack was better in his labouring class patients than in the white collar workers.

It seems to be beyond dispute that the better educated, and those who work with their brains, are more liable than their fellows to coronary disease. Why this should be is not clear. Reasonably it may be postulated that these people are exposed to a particular form of stress. If it could be proved that such stress may lead to metabolic change, perhaps to increased blood pressure, an important step might have been taken towards finding a cause for generalised atheroma. There would still require to be explained the strange predilection by which atheroma develops disproportionately in the coronary vessels, arising there not infrequently in the total absence of lesions elsewhere. According to Dock (1946) "the chief cause of death of American men during their period of highest earning capacity is to be sought in the peculiar susceptibilities of a few tenths of a gramme, or at most in a few grammes, of coronary intima." This selectivity of the pathological change is the kernel of the problem. The solution must await the results of further research conducted in the laboratory and requiring the assistance of expert biochemists.

and morbid histologists. From such recondite spheres mere speculation withdraws in modest confusion. In the meantime it is important that improved understanding by clinicians can already indicate the most likely victims. The appreciation is empirical but none the less valuable. What is it, then, that in the lives of professional men reduplicates so many of them to death from coronary disease? Are they more harassed than their less educated contemporaries? Do their ranks contain a monopoly of "worriers"?

Mental stress is elusive. It does not flaunt its dominion. Rather does it lurk within the shadows of life. The shapes which it assumes are infinite, and constantly changing, appearing to no two men alike. Trials which some might be intolerable are by others not even perceived. Is there some form of stress which weighs upon the "workers by brain" more heavily than upon the "workers by hand"? It is necessary to go more closely into these questions.

ORIGINS OF STRESS

Nowadays it is scarcely possible to open a newspaper without seeing a reference to the "stress" of modern existence. It seems to be held almost universally today that things are pretty tough—bad enough, in fact, to account for almost anything.

Most leading cardiologists regard this proposition with caution. There was a time when many of them seemed ready to welcome it as an explanation of the new forms of vascular disease. Paul White has admitted that in the first edition of his book *Diseases of the Heart* the element of stress as a factor in the pathogenesis of coronary disease was emphasised in italics, in the second edition the reference appeared in ordinary print, in the third it was deleted.

The trials of life have usually appeared exceptional to the generation called on to bear them. In 1910 Osler was already asking whether the "high pressure life" of the new century was making angina more common. To readers of Sackville West the Edwardian period now suggests the tranquillity of a Golden Age. In the slums, at the turn of the century, things were less happy, but Osler was not referring to the troubles of the poor. Time, like distance, lends enchantment. The magnolia-scented South of America was perhaps never quite so gracious as reputed of the days that are gone with the wind, nor England ever so "merrie" as she appears in retrospect. Mere survival during the Wars of the Roses and the Rebellion must have provided ordeals no less trying than the modern fish queue. It is tempting to agree with Master (1947) when he maintains that "stress and strain today is not greater than that which existed in ancient times during periods of war, great fires, plagues, and famine." Yet in those times coronary disease seems to have been rare.

Neither is it easy to trace evidence of particular stress in those who have developed heart-disease. Cassidy (1946) believed that most of his cardiac patients had lived "remarkably placid and sheltered lives." Levine (1929) has written "Concerning mental tension it is our impression that it is only of minor importance in coronary disease." Despite such scepticism the Spens Committee accepted the suggestion that it is the "strain of medical practice" that shortens the expectation of life in doctors—largely because of heart-disease.

What conclusion can be drawn from such varied opinions?

Mankind has always been subject to the constraints of human bondage. The question thus becomes: Has there developed during the last few decades, as a result of the increased "pace" of life, any special stress-bearing preponderantly upon the educated male section of the community? I believe that there has—and that its influence is becoming more widespread.

The essence of this stress is that it confronts its victim with an opposition which he feels himself driven to combat, and capable of surmounting, but only at the cost of extreme and long continued effort. In the end he is as likely as not to fail, to have it forced upon him, in fact, as Arlow (1945) suggests, that he is not as good as he thought. "Ambition minus reality equals neurosis," writes Beverley Nichols, quoting the words of a woman psychologist who thus identifies the source of many ills in modern America. Or it may be that a man's work is mentally distasteful to him. Experimentally such a situation has been investigated by Wolf and Wolff (1946), who found that a healthy individual when "asked to do a task he did not relish" at which he was convinced he would fail, exhibited a striking increase in blood pressure, which might persist for forty-eight hours.

The corroding effect of such endeavour is not usually revealed. The physician may miss it. Indeed he is seldom consulted and has little opportunity to discern it. Disasters such as flood and famine, war, and pestilence are outside the control of the individual. They do not produce the same tension. They are accepted—since there is no alternative. The victim becomes *débouillard*. He does what he can. If that should not suffice, he cannot blame himself. There is no element of competition. He need not feel that he has wasted half a lifetime, that if things had been a little different then he, and not Jones, would have won the promotion on which he had set his heart.

Not all temperaments are susceptible to this modern stress. Women are almost immune. It belongs to the office and the technician's bench, not to the kitchen or the Labour Exchange. For all sorts of women there is perhaps no greater anxiety than that of too often repeated pregnancies. The haunting possibility of what seems an almost intolerable further burden is seldom far from the thoughts of the average housewife. Yet should her fears be realised she is usually ready to accept what appears to be inevitable. No mental conflict develops. She is saved by her philosophy of acceptance. So also is the unskilled labourer—and for the same reason.

Today, more than ever before, the intuition of the manual labourer is to put his trust in collective action and wait for something to turn up. "The worker has not got the individualistic ethic," wrote Giles Romilly recently in the *New Statesman*, "his standards and values are co-operative, not competitive." Individual providence he regards with contempt. Whatever the size of his pay packet he makes a point of spending all that he earns. So long as things are going well for him, he takes inflated prices in his stride, scorning to limit his consumption of beer and tobacco while continuing to invest an average of ten shillings a week on horses, dogs, and football pools. He is content, if not with his lot, at least with himself. No sentiment of self-reproach assails his peace of mind. Neither is he troubled by ambition. He does not plague himself to master new techniques. Indeed he is profoundly suspicious of all change unless it promises shorter hours or higher pay. One of his deepest instincts is his distrust of rivalry in any form. To him the faintest breath of competition carries with it the odour of past exploitation. He wants neither more nor less than his fellows. Loyalty to his "own people" is his supreme concern. All his problems are laid upon the altar of this restricted solidarity. He knows it for his source of strength and he will have no truck with anything that might impair it. From time to time he is likely to decide in conjunction with his mates that it would best serve his interest to take a few days off. On these occasions it may well happen that a private soldier being required briefly to take his place, will learn between breakfast and lunch to perform

with equal efficiency the labour at which he has spent a life time. He will observe the fact without a pang.

The same tendency is plain among adolescents. It remains the dearest wish of most of them to leave school at the earliest possible moment, thus qualifying without delay for the quick rewards available in industry. Neither do they later evince the slightest desire to learn more than will barely suffice for their employment. A recent inquiry conducted by the West Hill Training College revealed much about the habits of teen-agers in Birmingham. The general impression was judged to be "depressing". The lives of these boys and girls, it was thought, must be "empty and barren". The organisers of the inquiry professed themselves "astonished" that the standard of writing and spelling should be so poor, and that the reading of a great many should be limited to "comics". Such findings are unlikely to surprise anyone who has lived with troops or worked in the wards of a hospital. As might have been expected, the cinema was shown to be universally popular among these young people, the whole group averaging three visits a fortnight. Expense proved no handicap. They had plenty of pocket money. Indeed about 13% of the boys were betting regularly each week. Of their newspapers the *Daily Mirror* easily topped the list. Not that they concerned themselves greatly with the happenings of the day. With few exceptions the most that might be said of their study of affairs was that if their interest could be momentarily captured by a comic strip, or a picture of a half-naked girl, it might prove possible so far further to entice their recalcitrant attention as to bring them to figure out a line or two of black type.

It is surely undeniable, from a cursory study of contemporary life in England, that most people, both young and old, feel no inclination whatever towards individual self-betterment. No doubt it has always been so. Illiteracy fifty years ago was far more widespread even than it is now. Despite the temporary setback of war it will no doubt continue to decrease. Neither does absence of personal ambition imply any lack of manifold stalwart virtues, though perhaps it is to be feared that the changed economic and political trends of the modern world will threaten increasingly those whose philosophy is that of acceptance. Orwell (1949) saw the workers of 1949 as the "proles" of 1984. They had undergone a subtle degeneration. "Heavy physical work, the care of home and children, petty quarrels with neighbours, films, football, beer, and, above all, gambling, filled up the horizon of their minds. To keep them in control was not difficult." But the proles, nevertheless, whatever their masters may have thought of them, were the only happy people in Oceania. One can be sure that, like their prototypes, they were little troubled by coronary disease.

How different is the attitude of the minority. During the last fifty years the progress of what Witts calls the Second Reformation has induced the stirrings of ambition in many young men who, in an earlier age, would have spent their lives in manual toil. No other possibility would have occurred to them. Today their newborn hopes have been fostered by increased facilities for secondary education. As a result these budding engineers, clerks, and craftsmen have found themselves entering into bitter competition with each other in an effort to secure scope for their new talents and consequent entry to the pathways of personal advancement. In this way new sections of the population have become exposed to the modern form of stress. The struggle which awaits them proves severe. Blacker (1949) points out that the aspirations so kindled are likely to become increasingly thwarted. There are not enough places to go round. To quote a university student: "There is a

sense of fighting all the time," with the consciousness that "it is vital not to let anyone get ahead." While the contest lasts poverty depresses the standard of living among these young men below that of the lowest paid manual worker. Of those that fail few can accept with equanimity the return to well-fed serfdom in factory, dock, or mine. They have lost their habit of acceptance. The memories of vanished hopes pursue them relentlessly in defeat. Nevermore can they escape their own attempt to strike out for themselves.

There remain too, in England, the tattered survivors of the former "middle classes," from whom it is now thought proper that resentful and idle mediocrity should exact every conceivable tribute. From the first these were the chosen victims of coronary disease, whether or not as the result of their way of life. Recently the many modern troubles which assail their domestic security have become disproportionately aggravated. In the words of Mabane (1949) "to all who pursue an independent life, and who by their ability and effort achieve a high earning capacity, the problem of provision for retirement and even more, provision for dependants on death, is a constant and gnawing anxiety."

At this half-way stage of the twentieth century there are, in fact, two Englands, but they are not the Englands referred to by Disraeli when he wrote of the Chartist in his novel *Sybil*, not the England of power and privilege on the one hand and poverty and constraint on the other. Rather does the division lie today between the few who still regard independence as the ultimate goal, striving towards it in circumstances of unprecedented difficulty, and the many who are prepared to surrender it in return for the nebulous rewards offered by the Welfare State. Only upon the few does modern life exert its particular stress, and from among them exact its fatal tribute.

CONCLUSION

Here then is a significant parallel. New conditions of stress, and a heavy preponderance of coronary disease, have in recent years arisen concurrently within the same small sections of civilised communities. These two developments have been present long enough for it to be possible that the first should be cause and the second effect. It is, in fact, reasonable to identify sufferers from coronary disease as the selected victims of modern stress. Little more can be said at present. Nothing is proved. Nevertheless, the coincidence is remarkable.

REMARKABLE FEAT OF ENDURANCE

BY A YOGI PRIEST

RUSTOM JAL VAKIL

M D Lond, M R C P, D T M & H

REMARKABLE feats of endurance, often bordering on fantastic or miraculous, are by no means rare in India. In spite of their frequency, these endurance of *yogis* or *sadhus* continue to excite our admiration and disbelief. So far as I am aware, very few, if any, scientific studies have been made in an attempt to cover the physiological explanation of them. The present report represents but an amateurish attempt to amuse one of these feats that I had the interesting experience of following up at close quarters.

On Wednesday, Feb 15, 1950, at precisely 5 P.M., the first, or *pratyak*, phase (often called the *bana samadhi*) of the *yogic* feat began when Shri Ramdasji, an emaciated *sadhu* of hypochondriac habitus and middle age, entered an airtight subterranean concrete cubicle on one of the main highways of Bombay city. The act was witnessed at close quarters by over 10,000 spectators.

The walls of the cubicle, which measured $5\frac{1}{2}$ by $4\frac{3}{4}$ ft., were constructed of slabs of concrete 7 in thick firmly cemented at the edges to make the cubicle both airtight and light-tight, the total air capacity of the cubicle worked out at 216 c ft. The lid or roof of this cubicle, which was cemented in place afterwards, was another slab of concrete 3 in thick. The walls of the concrete cubicle were lined or studded externally with thousands of iron nails 3 in long, most of them old and rusty.

After the *sadhu* had sat down with legs crossed in the subterranean chamber, the lid was put on and sealed with cement. Enclosed within this shell of concrete, the *guruji*, according to his disciples and followers, is supposed to remain in a state of suspended animation and meditation or *samadhi*.

Exactly fifty six hours after the start of the *samadhi*, a narrow opening was bored into the lid of the cubicle, and with the aid of a fire hose about 1400 gallons of water was introduced into the concrete cubicle, the narrow opening being subsequently sealed. Thus began the second or wet phase (the *jala samadhi*) of the *yogic* feat, this lasted about six and a half hours, the *sadhu* remaining all this time within the cubicle in a state of almost complete immersion.

At 8 A.M. on Sunday morning the concrete lid of the cubicle was detached and the *yogi* lifted out of the water, placed on a high and specially erected *pandal*, and immediately subjected to a clinical examination by me. He was in a state of semi-consciousness or stupor with closed eyes and flaccid limbs. The pupillary reflexes were present but sluggish. The pulse, whose rate was quite regular at 80 per minute, was of low volume. The blood pressure was 112/78 mm Hg, and the respirations were only 8-10 per minute and regular. After a few whiffs of smelling salts the *sadhu* opened his eyes and took heed of his surroundings. Except for some scratches and cuts over the lower extremities and trunk he appeared none the worse for his gruelling experience. He had remained within the concrete cubicle for just over sixty two hours.

COMMENTS

In connection with this *yogic* feat it is interesting to recall that J B S Haldane once enclosed himself in an airtight tank for an hour apparently receiving no harm. In his opinion the oxygen requirement of a man doing light work is about 24 c ft per twenty four hours, whereas that of a man lying perfectly still is only about 12 c ft a day or $1\frac{1}{2}$ c ft an hour. According to Haldane's figures the *yogi* could have remained alive within his concrete cubicle of 216 c ft capacity for eighty six hours, whereas he spent only sixty two hours in it.

Although these physiological considerations may rob this *yogic* feat of much of its mystery, nevertheless one cannot but admire the courage and endurance of this frail and emaciated man who allowed himself to be encased within an airtight chamber, lined with 3 in nails, for sixty two hours.

THE KING'S FUND

Hospital Costing System

PRESIDING at a meeting of the General Council of King Edward's Hospital Fund for London on Dec 13, the Duke of GLOUCESTER said that people still sometimes ask what the Fund is doing today. Some seem to find it almost incredible that it should be free to use its own discretion, and that its help should be constantly sought. But it is, and today the Fund is doing more direct practical work to help hospitals and their patients than ever before. It is recruiting nurses, arranging the admission of patients, designing new kitchens, and advising on the latest equipment for any hospital that needs the help. In addition to all this, the Fund is training future hospital administrators, medical records officers, and others, it is investigating the finance systems of the hospitals, and is providing relief accommodation for hospital beds. In all these things its activities are directed towards improving the hospital service while keeping the cost down.

The fact is that the new administrative arrangements are on their trial, and some time must elapse before it can be assumed that they are providing a service that is both humane and economical. But the new set up has come to stay, and the Fund is anxious to do all it can to help. We have, at the express invitation of the Ministry of Health, undertaken an extensive costing investigation at a number of hospitals, and I should like to enlarge a little upon it. The Fund has long possessed much information about the organisation and management of hospitals, their finances, and accounting methods. In 1939 the scope of its activities was extended, and at the time of the passing of the National Health Service Act budgets were becoming fairly common, stores records, and in some cases stores accounts also were being introduced, quantity statistics were prepared, and a number of hospitals were considering the introduction of cost accounts. The present investigation therefore, may be regarded as an extension of an existing activity of the Fund rather than a new one. It will, however, go much further than any investigation hitherto carried out. Its purposes are to investigate the existing systems of accounting to design and install a costing system, and finally to supervise its operation in a limited number of hospitals. When satisfied as to its practicability the Fund, with the Nuffield Provincial Hospitals Trust, which is carrying out a similar investigation in the provincial hospitals, will present a joint report to the Ministry of Health.

The system will at the same time bring about the all essential integration of finance and administration, the lack of which at present is seriously impairing the efficiency of hospital administration.

Referring to other activities of the Fund, the Duke said that it was expected that the Hospital Administrative Staff College would open in April, 1951. The rehabilitation of the many convalescent homes dotted over the southern counties was now largely accomplished. Thanks to the substantial allocations made by the Fund and to the energetic work put in by the convalescent homes committee, under the chairmanship of Sir Henry Tidy, most of the homes were functioning in a way that would certainly not have been possible without help from the Fund. A detailed survey was being made of cases in hospitals needing convalescence, and the committee hoped to get definite figures which would dispose of the uncertainty which had for years surrounded this subject.

The distribution committee had this year been able to help several of the hospitals lying outside the National Health Service with special grants to tide them over difficulties, and—more important in the long run—with sound advice which should lead to balanced budgets.

The provision of a number of homes for the aged sick had proved no easy task. Difficulties in the way of acquisition of suitable properties could not always be foreseen and had to be solved as they came to light. The Fund had, however, already opened three homes, and a further seven properties were in process of adapta-

with equal efficiency the labour at which he has spent a life time. He will observe the fact without a pang.

The same tendency is plain among adolescents. It remains the dearest wish of most of them to leave school at the earliest possible moment, thus qualifying without delay for the quick rewards available in industry. Neither do they later evince the slightest desire to learn more than will barely suffice for their employment. A recent inquiry conducted by the West Hill Training College revealed much about the habits of teen-agers in Birmingham. The general impression was judged to be "depressing." The lives of these boys and girls, it was thought, must be "empty and barren." The organisers of the inquiry professed themselves "astonished" that the standard of writing and spelling should be so poor, and that the reading of a great many should be limited to "comics." Such findings are unlikely to surprise anyone who has lived with troops or worked in the wards of a hospital. As might have been expected, the cinema was shown to be universally popular among these young people, the whole group averaging three visits a fortnight. Expense proved no handicap. They had plenty of pocket money. Indeed about 15% of the boys were betting regularly each week. Of their newspapers the *Daily Mirror* easily topped the list. Not that they concerned themselves greatly with the happenings of the day. With few exceptions the most that might be said of their study of affairs was that if their interest could be momentarily captured by a comic strip, or a picture of a half-naked girl, it might prove possible so far further to entice their recalcitrant attention as to bring them to figure out a line or two of black type.

It is surely undeniable, from a cursory study of contemporary life in England, that most people, both young and old, feel no inclination whatever towards individual self-betterment. No doubt it has always been so. Illiteracy fifty years ago was far more widespread even than it is now. Despite the temporary setback of war it will no doubt continue to decrease. Neither does absence of personal ambition imply any lack of manifold stalwart virtues, though perhaps it is to be feared that the changed economic and political trends of the modern world will threaten increasingly those whose philosophy is that of acceptance. Orwell (1949) saw the workers of 1949 as the "proles" of 1984. They had undergone a subtle degeneration. "Heavy physical work, the care of home and children, petty quarrels with neighbours, films, football, beer, and, above all, gambling, filled up the horizon of their minds. To keep them in control was not difficult." But the proles, nevertheless, whatever their masters may have thought of them, were the only happy people in Oceania. One can be sure that, like their prototypes, they were little troubled by coronary disease.

How different is the attitude of the minority. During the last fifty years the progress of what Witts calls the Second Reformation has induced the stirrings of ambition in many young men who, in an earlier age, would have spent their lives in manual toil. No other possibility would have occurred to them. Today their newborn hopes have been fostered by increased facilities for secondary education. As a result these budding engineers, clerks, and craftsmen have found themselves entering into bitter competition with each other in an effort to secure scope for their new talents and consequent entry to the pathways of personal advancement. In this way new sections of the population have become exposed to the modern form of stress. The struggle which awaits them proves severe. Blacker (1949) points out that the aspirations so kindled are likely to become increasingly thwarted. There are not enough places to go round. To quote a university student: "There is a

sense of fighting all the time," with the conscious that "it is vital not to let anyone get ahead." While the contest lasts poverty depresses the standard of living among these young men below that of the lowest-paid manual worker. Of those that fail few can accept with equanimity the return to well-fed serfdom in factory, dock, or mine. They have lost their habit of acceptance. The memories of vanished hopes pursue them relentlessly in defeat. Nevermore can they escape their own attempt to strike out for themselves.

There remain too, in England, the tattered survivors of the former "middle classes," from whom it is now thought proper that resentful and idle mediocrity should exact every conceivable tribute. From the first they were the chosen victims of coronary disease, whether or not as the result of their way of life. Recently the many modern troubles which assail their domestic security have become disproportionately aggravated. In the words of Mabane (1949) "to all who pursue an independent life, and who by their ability and effort achieve high earning capacity, the problem of provision for retirement and even more, provision for dependants on death, is a constant and gnawing anxiety."

At this half-way stage of the twentieth century there are, in fact, two Englands, but they are not the Englands referred to by Disraeli when he wrote of the Chartist in his novel *Sybil*, not the England of power and privilege on the one hand and poverty and constraint on the other. Rather does the division lie today between the few who still regard independence as the ultimate goal, striving towards it in circumstances of unprecedented difficulty, and the many who are prepared to surrender in return for the nebulous rewards offered by the Welfare State. Only upon the few does modern life exert its particular stress, and from among them exact its fatal tribute.

CONCLUSION

Here then is a significant parallel. New conditions of stress, and a heavy preponderance of coronary disease, have in recent years arisen concurrently within the same small sections of civilised communities. These two developments have been present long enough for it to be possible that the first should be cause and the second effect. It is, in fact, reasonable to identify sufferers from coronary disease as the selected victims of modern stress. Little more can be said at present. Nothing is proved. Nevertheless, the coincidence is remarkable.

Public Health

OUTBREAK OF FOOD-POISONING DUE TO SALMONELLA ABERDEEN

WILLIAM BROCKBANK

M.A., M.D. Camb., F.R.C.P.

PHYSICIAN IN CHARGE OF A UNIT AND DEAN OF CLINICAL STUDIES, ROYAL INFIRMARY

C. METCALFE BROWN

M.D. Glasg., D.P.H.,

Barrister-at-Law

MEDICAL OFFICER
OF HEALTH

M. T. PARKER

M.B. Camb.,

Dipl. Bact.

DIRECTOR, PUBLIC
HEALTH LABORATORY

MANCHESTER

In the summer of 1949 a widespread outbreak of infection due to *Salmonella aberdeen* occurred as a result of the consumption of meat pies manufactured in Manchester and bought from different branches of one catering firm. Of the 50 cases 29 occurred locally (Manchester outbreak) and the rest in a party of scouts who ate the pies on their way to Scotland (Torridon outbreak). Since infections with this organism seem to be rare, we thought it desirable to publish our findings.

THE MANCHESTER OUTBREAK

On the evening of July 28, 1949, the Public Health Laboratory was informed of 4 cases of suspected food poisoning in two households in an area to the south-east of Manchester, and that meat pies bought from the local branch of a Manchester firm were thought to be responsible. A specimen of faeces and the unconsumed portion of a pie were received at the same time. Next morning it was clear that an organism of the salmonella group was responsible. Within a few hours reports of further cases in two other areas on the outskirts of Manchester were received. During the next few days specimens of faeces from several patients and the remainder of a second pie were examined. An apparently identical salmonella was isolated from all.

In the meantime the divisional medical officers of the affected areas telephoned all the local practitioners to seek information of other cases, and several further groups were discovered. In addition, 1 person infected with the same organism who denied eating any of the suspected pies was found. All subsequent attempts to trace the source of his infection failed.

Inquiries in Manchester revealed that the pies causing illness had been made on July 26, and sold by twelve branches of the firm, 206 pies and 450 sausage rolls had been distributed to the branches and practically all sold. As a result of all inquiries, 29 cases in eleven family groups were discovered: all the patients had eaten pies made on the same day. No cases could be attributed to the sausage rolls.

The main symptoms were diarrhoea and vomiting, but the common presence of pyrexia, malaise, and pains in the limbs had suggested a salmonella infection. Five patients were admitted to hospital. One interesting feature was a case of acute gastro-enteritis in a dog fed with part of a pie which gave rise to 2 human cases.

It is instructive to note the circumstances which led to the discovery of the 29 cases. Eighteen were traced through inquiries by medical officers of health after the existence of the outbreak had been established. Of the other 11, 3 came to light when a practitioner sought assistance in securing their admission to hospital, and 4 because they were relations of members of a public health department, 1 was diagnosed by blood culture after appendicectomy. 3 were reported by practitioners to a medical officer of health by telephone. None were notified.

Causative Organism

An organism of the salmonella group was isolated from the faeces of 21 patients and from the blood of 1 other. It was also obtained from thirteen meat pies and 1 symptomless excreter. It was isolated at about the same time from the faeces of 1 other patient whose connection with the outbreak was doubtful.

Twenty-eight strains were examined in detail and found to have identical characteristics. They were gram negative mobile bacilli which grew well on ordinary media. They gave acid and gas in glucose, maltose, mannitol, dulcitol, arabinose, rhamnose, xylose, and trehalose in eighteen hours, but not in lactose, sucrose, salicin, or inositol in fourteen days. They were all H₂S positive and indole negative, and did not liquefy gelatin. They were not agglutinated by salmonella O sera of groups A, B, C, D, or E. It was subsequently found that they were agglutinated to full titre by an *S. aberdeen* O serum. On first isolation they were largely in the specific phase and were agglutinated by a *S. typhimurium* H serum. Six strains were submitted to the Salmonella Reference Laboratory at Colindale. Dr Joan Taylor reported that they had the antigenic formula XI 1 $\longleftrightarrow$ 1, 2, 3 and were therefore *S. aberdeen*.

TORRIDON OUTBREAK

A group of 18 scouts and 9 adults, including one of us (W.B.), left Manchester on the evening of July 27 bound for a walking holiday in Scotland. They took with them thirty small meat pies packed in a biscuit tin. These were eaten for lunch in the train between Inverness and Achnasheen at about 12.30 p.m. on July 28. Sixteen boys and 6 adults ate at least part of a pie, some more than one.

In the afternoon of the same day camp was pitched in a rather exposed position at the eastern tip of Loch Torridon, and a latrine was dug in a distant part of the field. It began to rain heavily that evening and continued for six days with occasional strong gales. One or two members of the party had some diarrhoea that evening, but the existence of an epidemic was not realised until those on duty rose to prepare breakfast. It was then clear that something was wrong. There were several pools of vomit and at least one pair of soiled pyjamas lying outside the tents. Twenty-one of the party had diarrhoea, vomiting, and abdominal pain to a greater or lesser extent, and many of them were feverish. All had eaten at least part of a pie, and only one pie eater was unaffected.

During the next two days there was little improvement in most of the victims, and on July 31 two scoutmasters and six boys had temperatures of 101°F or more. Diarrhoea was still apt to be sudden and violent. At this stage Captain Gunter, of Torridon House, kindly arranged for the worst eight cases to be transferred to the top floor of his house with two able-bodied adults to look after them. An attempt was made to consult the local doctor, but he was away on a long distance call up the loch.

On Aug. 1 the doctor arrived. It was then decided to send a scoutmaster and a boy who were still feverish to Invergordon Isolation Hospital. One more boy was transferred from the camp to the house. Next day two of the boys in the house had relapsed with temperatures of 103°F, and one other was still feverish. All three were transferred to hospital.

The camp was due to move next day to the neighbourhood of Loch Maree and, the weather still being very bad, a search was made for covered accommodation. On Aug. 3, therefore, the remnants of the party were moved by bus to a small corrugated iron drill hall at Kinlochewe. There were still two obvious invalids who, although afebrile, were lethargic and looked poorly. The rest seemed fully recovered.

tion The British Red Cross Society and other voluntary bodies which had undertaken the management of the homes had coöperated wholeheartedly with the hospital authorities and the Fund in all the preliminary work. This was essentially a pilot scheme, with two objects to give some of the old people who must otherwise be hospital cases more home like care, and at the same time to get the beds in the hospitals free for others who too often cannot obtain admission.

Sir EDWARD PEACOCK, treasurer, said that during the year £230,000 had been spent on ordinary expenditure, and £92,000 on capital and non recurrent items, whereas the disposable sum upon which the Fund could rely was some £300,000 a year or a little more. A further £100,000 had been received from the Nuffield Trust for the Special Areas, and was being added to capital. The late Lord Wakefield had made the Fund one of the residuary legatees of his estate, with an instruction that any sum received should be treated as capital, and £200,000 had recently been received.

Sir ARCHIBALD GRAY, chairman of the distribution committee, speaking of the nine homes now being provided for the aged sick, said that the Fund was anxious to emphasise that they were intended, not for the completely bed ridden, but for "frail ambulant" who could enjoy the attractive gardens and other amenities of the houses.

Disabilities

57 OLD AGE

WHEN does old age start? I feel inclined to extend the normal three score and ten to 75. Life today is longer and, granted reasonable health and mental freshness, no one should feel really aged before then. Of course, when no more than five and forty, a man with a family growing up may remark, "I am getting on." This, however, is a pose, and the next day, to prove his fitness, he will take a twenty mile walk. After 60 he may, as a precaution, take things easier, but this without a trace of certain symptoms which will appear later. He may escape serious accident or illness and be spared one or other of those bodily visitations which call for drastic surgical treatment. Yet sooner or later there comes a day when he realises that age is upon him. Yes! And suddenly he feels a wave of intimate sympathy with the frail, for whom previously he had a lordly pity.

The first warning is often ignored. Probably the patient has neglected to be perfectly frank with his doctor. There has been a momentary shock, but equilibrium is restored, and in the absence of any perceptible change he proceeds on his journey. Years may pass before another red light appears. My own came at about the 75 contour line while I could still carry on normally. What is the reaction when deterioration can no longer be ignored? I leave on one side the question of bodily or mental collapse. Also I accept as normal the slow response of muscles and the hesitancy of functional organs. The man I have in mind is still mentally vigorous, still full of life, with a steady hand and good eyesight, who knows clearly that, now, he is old. Secretly he resents it. Intelligence, imagination, enthusiasm, capacity for work, all are there, but (and it is a big but) control is waning. This applies to head and limbs alike, for these are in mutual sympathy.

Firstly, in respect of the head there may be no sudden vertigo, but there is a precautionary reluctance to turn round or stoop down. An upward glance or a sharp turn of the head provokes momentary giddiness, while a downward bend to pick up something reveals a lack of correlation between head and knee muscles. The worst trial of all is to stand still indefinitely while a lady discourses at large on the movements of her

relations. This question of balance is interesting because of its contradictions. Rough hilly ground would disconcert me, walking a 9 inch plank over a stream would not unnerve me, over a wooden or wire fence I could climb without hesitation. But give me a streak of ice on a wintry road, set me on a chair without a supporting hand hold, and I should shrink at some conspiracy between head and limb would warn me. To a doctor one does not communicate this kind of childish weakness. Can determination overcome it? Or is it wiser to capitulate gracefully?

Then, on the physical side, there comes awareness of the exercise of any kind produces tiredness, and this is emphasised by shortness of breath. There may be no pain and no stiffness in the muscles, but just a weariness, an inclination to get out of the way and rest. And when the brain is active again you resent this, you are still nursing the unconquerable hope, still clinging to the delusion, that you are not old. It is long since you felt an inclination to run, but you do hope for time to walk without threat of faintness. But that lily of 1000 over the bridge, that flight of steepish steps, that parcel of books you are carrying, that window you wish to open, that table you want to move! Tackle all of any—and some obscene little demon laughs in your ear.

It is here, too, that the mental side comes in. From ordinary mental overwork a man may seek refuge in physical exercise, but on reaching the stage where physical work is beyond him, where can he turn to recreation? It is easy to suggest read, write, or resort to chess or bridge, but at 75 or 80, with little capacity for physical exercise, can the mind be rested by mental exertion greater than it had to bear between the ages of, say, 20 and 70? Ordinary business or professional pursuits provide a routine which eases the strain, but in retirement routine is swept from the daily schedule. Companionships might do much to stimulate, but environment changes as age approaches. Contemporary drop by the way, and if retirement has involved a change of scene new companionships are not quickly acquired nor are they quite so intimate. Thus age has often to be passed in comparative seclusion.

Apart from trifling lapses of memory or moments of absent mindedness, a man of 80 may feel in full possession of all his former mental faculties and yet feel honest enough to ask himself how far is this justified and how much is mere wishful thinking? If he attempts to write a book or an article, or to deliver an address will the impression left on reader or hearer be that of virility or senility? He cannot tell, but the secret dread of disillusionment is ever present. My own experience of men is that even in age the capacity for study, research, concentration, analysis, and interpretation may remain unimpaired. At 80 a man may show an inclination to suspend judgment on matters of the moment, but in thought he may have much to contribute. Where weakness may emerge is in yielding to mental restlessness—thus at least in the case of one who has led a very active life and who chafes at enforced inactivity. Restlessness, too, unless combated, may easily develop into impatience and possibly depression, and as the man is usually aware that his blood pressure is above normal he is conscious that impatience reacts on bodily as well as on mental fitness.

Age presents many problems, but to the old man whose mind remains active the greatest is this. At his desk, fully occupied, he feels fit, calm, and contented. He needs recreation, however, as well as rest. When the body can no longer provide the exercise that would afford the needed recreation, is there any other compensation?

** This article concludes our present series on Disabilities. We are hoping to publish a selection from them in book form.—ED. L.

1 in Manchester and 5 in Scotland) Very little information was obtained about the rate of clearance of the organism from the faeces. In only 3 patients whose occupations were connected with the food industry were regular specimens examined for a month. At the end of this time 2 were still excreting the organism and 1 had become negative at about the seventeenth day after infection.

The organism was isolated from blood cultures in all cases in which it was attempted when the temperature was 99°F or higher. Two of these occasions were during relapses. Serum agglutinations were done in a few cases at the second week of disease and a high titre of agglutination of *S. abderdeen* O and *S. typhi* murium H specific was obtained. The series was too small and selected so the results to be of much value. Total and differential white-cell counts in a few of the cases showed either normal values or mild leucopenia with relative lymphocytosis.

FACTORS INFLUENCING ATTACK RATE AND SEVERITY OF INFECTION

A total of 238 pies and 450 sausage rolls made on July 26 were distributed for sale: about 20 of the pies were large (1 lb.) and 210 small (4 oz.). Of the eleven family groups of cases in and around Manchester six with 21 cases followed the consumption of seven large pies. Four groups with 7 cases were due to ten small pies. Eaters of large pies consumed an average of a third of a pie each, as compared with a whole pie each for the eaters of small pies. Thus the apparent attack rate for large pies was about 30%, and for small pies between 3 and 4%. The true rates for both groups were certainly higher than this, but it seems that the risk of illness from large pies was greater than that from small pies. The attack rate within the family group was 100% for large pies and about 70% for small pies.

In the Torridon outbreak the situation was quite different. Here only small pies were consumed but they had been kept for a further twenty-four hours at atmospheric temperature. The high apparent attack-rate (95%) may well have been due to the presence of medical supervision. However if this had been the only difference between the scouts and the Manchester group one would have expected a higher proportion of mild cases among the former. In fact, 5 of the 8 severe cases and only 3 of the 12 mild cases occurred at Torridon, and there is little doubt that the average attack was more severe in this group.

The quantity of pie eaten by the patients varied from 1 to 12 oz. Of the 49 cases in which information is available the average consumption was 4.9 oz. for mild cases, 4.4 oz. for moderate cases, and 4.1 oz. for severe cases.

The patients were aged 2½-65 years and of either sex. There was no obvious association between age and severity of attack within these limits.

INVESTIGATION OF OUTBREAK

On July 29 the bakery at which the pies had been made was inspected. It was a large modern plant employing about 100 persons. The standard of cleanliness was high, and good sanitary accommodation was provided.

Preparation of Pies

The meat used for both pies and sausage rolls was supplied ready for use by a wholesale butcher. It had been minced, seasoned, and mixed with 'filler'. A consignment of 80 lb. was received each Monday, Tuesday, Wednesday and Thursday, and used the same day.

The pastry was made from flour, cooking fat, salt and water. The dough was 'blocked out' on a modern machine and the prepared meat was hand-

filled into the "blocks" by three female employees. The same machine was also used for "crimping" on the tops of the pies, which were then placed in the oven for 25-30 minutes at 450-475°F. The gelatin was added after baking. Sheet gelatin was soaked in water, dissolved in fresh boiling water, and filled into the pies from a jug as soon as it had partially cooled. No eggs or egg products were used.

The pies were stored at room-temperature overnight and taken next morning to the twelve branches for sale. They were normally sold on the day of receipt and with few exceptions eaten on the same day.

Bacteriological Investigations at Bakery

None of the pie makers had recently had any gastro-intestinal disturbance. One of the bakers was absent from work with diarrhoea and vomiting but he had taken home some of the pies from the incriminated batch. He and his family had become ill after eating them.

The bakery was first visited on a Friday, when no pies were available for sampling. Owing to the Bank Holiday, specimens of faeces from the three pie makers were not obtained until Aug. 2. All were negative except that of a middle-aged woman, from which a scanty growth of *S. abderdeen* was obtained. Three subsequent specimens taken between Aug. 8 and 12 were negative. None of her family gave any history of gastro-enteritis, and their faeces were negative. The woman admitted that she was in the habit of eating pieces of raw meat while filling the pies.

Specimens of sheet gelatin, washings from the tin in which the gelatin was softened and a mouse trapped in the bakery were examined bacteriologically with negative results. Specimens of six batches of pies made between Aug. 5 and 15 were bacteriologically negative.

Butcher's Shop

The meat used for the preparation of the pies consisted of five parts of hindquarter beef and one of fat pork. It had been received on July 23 and prepared two days later. Conditions at the shop were very unsatisfactory, and legal proceedings were successfully taken against the firm. It was impossible, however, to establish that the infection had been introduced from this source, or to find out whether meat from a single carcass had been used for the preparation of mince on successive days.

Samples of minced meat and of debris from the mincing machine and from the crevices of the cutting-up table on July 29 were negative bacteriologically. The faeces of all four employees and specimens of prepared pie-meats collected on six subsequent occasions were also examined without result. No salmonellae were isolated from the only mouse trapped on the premises.

Other Investigations

On July 29 a divisional medical officer took possession of eighteen meat pies and seven sausage rolls which were on sale at one of the branches. These were stated to have been made on July 28—i.e., two days after the batch responsible for the outbreak—and subsequent investigations confirmed this. Two of the pies were sent to the laboratory and the rest stored in the basement of a town hall. A heavy growth of *S. abderdeen* was obtained from both of the pies. Unfortunately the rest of the batch could not be secured until Aug. 2, but in spite of having been five days at room temperature and become heavily contaminated with moulds the organism was isolated from nine of the sixteen pies. None was obtained from any of the sausage rolls. It is therefore certain that batches of pies other than the one responsible for the outbreak were contaminated with *S. abderdeen*.

DISCUSSION

S. abderdeen was first described by Smith (1934), who isolated it from a sporadic case of mild gastro-enteritis.

The weather having now improved, two expeditions were organised. These did much to improve the spirits of the party, but unfortunately one of the boys on his return complained of headache and a recurrence of abdominal pain and had a temperature of 102°F. His recovery being slow, he was sent to hospital on Aug. 6. One other boy, who usually abounded in energy, remained strangely lethargic though perfectly happy and had not fully recovered when the party returned home. The party began the journey home on Aug. 16, picking up five of the six hospital patients on the way. Some of the latter had clearly lost a lot of weight and looked pallid. In two cases it was well into October before recovery was complete.

Only for two short periods did any of the patients cease real anxiety while at Torridon. On the first day a boy complained of pain and was tender over his appendix for a few hours, and four days later he suddenly developed a generalised urticarial eruption, which was fortunately only short lived.

Subsequent inquiries showed that the pies responsible came from the same day's baking as those causing the outbreak in the Manchester area, but they were eaten about twenty-four hours later.

Salmonella aberdeen was isolated from the faeces of 5 and from the blood of 2 of the 6 patients in Invergordon Isolation Hospital.

CLINICAL CONDITION OF MANCHESTER AND TORRIDON PATIENTS

The 21 Torridon patients were under continuous medical supervision, and full clinical histories are available. The county *MOH* of Ross and Cromarty has kindly allowed us to make use of the case notes from the Invergordon Isolation Hospital. With the help of other medical officers of health and hospital physicians it has been possible to collect clinical histories of 26 of the 29 cases occurring in and around Manchester. Three were diagnosed after a considerable interval, and they have not been included in the following analysis. The single case in which there was no history of eating a meat pie has also not been included.

Most of the patients had gastro-enteritis with fever. In over half the cases the most prominent symptoms were diarrhoea and vomiting, but these symptoms were usually accompanied by a feeling of general malaise and pains in the limbs and back or headache. There were other cases in which the gastro-intestinal disturbance was less prominent and the appearances were very like those of a mild enteric fever. In two cases there was no gastro-enteritis and the symptoms were those of a pure septicemic disease. There were also cases whose symptoms suggested an acute surgical abdominal condition. Several of the more severe cases had short febrile relapses with or without a return of the gastro-enteritis.

Incubation Period

The average incubation period of all the cases was 13 hours (range 5-24 hours). There was no significant difference between the average incubation period for those eating pies on July 27 and 28.

Cases with Gastro-enteritis

Of the 47 patients, 45 had some diarrhoea, and of these 33 had vomiting, 27 had abdominal pain, and 18 had vomiting and abdominal pain, 4 had diarrhoea only. Other symptoms included headache (13 cases), generalised aches and pains (11 cases), and lassitude (4 cases). The temperature was recorded in 40 cases and was raised in 36 of these. It exceeded 100°F in 29 cases, 101° in 16, 102° in 10, and 103° in 4. The highest recorded was 104.6°F. The presenting symptom was diarrhoea in 20 cases, vomiting in 3, diarrhoea and vomiting in 5, abdominal pain in 11, headache in 3, and anorexia in 3.

Twelve cases were classified as mild, 27 as moderate, and 8 as severe. Five of the 8 severe cases were in the Torridon outbreak. The duration of illness varied greatly. 5 patients were incapacitated for 1 day only, 17 for 4-5 days, 9 for 6-7 days, 3 for 10 days, 1 for a fortnight, 5 for 3 weeks, 4 for 4 weeks, 1 for 5 weeks, and 2 for 10 weeks.

The following cases illustrate the varieties encountered.

Mild a man, aged 49, ate one small pie at 1.30 p.m. on July 28. There were no symptoms until 7 a.m. next day, when he passed a fluid stool. For forty-eight hours he was lethargic with slight fever (maximum 99.2°F) but could get about with an effort. After this he felt fully recovered but continued to pass two fluid stools daily until Aug. 2.

Moderate a scout, aged 15, awoke feeling sick and dizzy eleven hours after eating one small pie. He vomited several times during the next forty-eight hours and had diarrhoea for four days. He was feverish for three days (maximum 100°F). Recovery was complete after four days.

Severe a man, aged 23, ate one small pie at 1.30 p.m. and two more at 5.15 p.m. on July 28. At 10 p.m. the next night he woke with violent abdominal pains and diarrhoea. Fever (101-102°F) and diarrhoea persisted for five days. He was sent to hospital on Aug. 1 but was afebrile on arrival and remained so. He was discharged on Aug. 16 having lost a stone in weight. He looked poorly and was easily tired and short of breath. He was not fit to play energetic games until the middle of October.

Severe with relapses a scout, aged 17, became ill seven and a half hours after eating one small pie. Diarrhoea persisted for five days and vomiting for two days. He was feverish for two days (101°F), but the temperature was normal by the evening of Aug. 1. Next morning he had relapsed (102.6°F) with a tender distended abdomen. He was sent to hospital where *S. aberdeen* was isolated from his blood. His temperature became normal on Aug. 6, but rose to 99°F on Aug. 14, and 15. He was detained in hospital for three weeks and lost 1½ st. He was short of breath on exertion and easily tired for several weeks afterwards. He was not fully recovered until early October.

Cases Simulating Appendicitis

A girl, aged 13, developed acute vomiting and abdominal pain in the early hours of the morning about fourteen hours after eating a small pie. In the afternoon she was sent to hospital, where acute appendicitis with peritonitis was diagnosed. At 11 p.m. her abdomen was opened, the appendix was knicked and bound to the caecum by adhesion and was moderately inflamed. The mesenteric glands were enlarged. Next day the temperature was 103°F and the patient passed two motions. *S. aberdeen* was grown from blood collected on this day. Fever persisted until Aug. 8, and the patient was discharged on Aug. 20.

A scout, aged 15, became ill with headache and abdominal pain twenty hours after eating a small pie. His temperature was 100°F, and he was tender and rigid over the appendix. In view of the other cases in the camp it was decided not to send him to hospital for the time being. The diarrhoea came on soon afterwards, and the localised tenderness vanished.

Cases of Pyrexia without Gastro-enteritis

Only 2 such cases occurred, and 1 of these had some abdominal pain.

A woman ate half a large pie, and after twenty-one hours had a headache with a temperature of 100°F, which lasted twenty-four hours. There was no diarrhoea or vomiting. This case was not confirmed bacteriologically, but *S. aberdeen* was isolated from the remainder of the pie and from the faeces of another person who had a severe gastro-enteritis after consuming half as much as this patient had.

A scout, aged 17, ate half a small pie on July 28. He developed headache, abdominal pain, and fever twenty-four hours later. At no time did he vomit or pass a fluid stool but *S. aberdeen* was isolated from the faeces. The fever (101°F) lasted six days, and he was the first to be sent to hospital. Convalescence was slow, and he was not fully recovered for a month.

BACTERIOLOGY

The causal organism was isolated from the faeces of every patient from whom a specimen was examined.

1 in Manchester and 5 in Scotland) Very little information was obtained about the rate of clearance of the organism from the faeces. In only 3 patients whose occupations were connected with the food industry were regular specimens examined for a month. At the end of this time 2 were still excreting the organism and 1 had become negative at about the seventeenth day after infection.

The organism was isolated from blood cultures in all cases in which it was attempted when the temperature was 99 F or higher. Two of these occasions were during lapses. Serum agglutinations were done in a few cases in the second week of disease and a high titre of agglutination of *S. abderdeen* O and *S. typhimurium* H specific was obtained. The series was too small and selected for the results to be of much value. Total and differential white-cell counts in a few of the cases showed other normal values or mild leucopenia with relative lymphocytosis.

FACTORS INFLUENCING ATTACK RATE AND SEVERITY OF INFECTION

A total of 238 pies and 450 sausage rolls made on July 25 were distributed for sale: about 20 of the pies were large (1 lb.) and 210 small (4 oz.). Of the eleven main groups of cases in and around Manchester six with 21 cases followed the consumption of seven large pies. Four groups with 7 cases were due to ten small pies. Eaters of large pies consumed an average of a third of a pie each, as compared with a whole pie each for the eaters of small pies. Thus the apparent attack-rate for large pies was about 30% and for small pies between 3 and 4%. The true rates for both groups were certainly higher than this, but it seems that the risk of illness from large pies was greater than that from small pies. The attack-rate within the family group was 100% for large pies and about 70% for small pies.

In the Torridon outbreak the situation was quite different. Here only small pies were consumed, but they had been kept for a further twenty-four hours at atmospheric temperature. The high apparent attack-rate (95%) may well have been due to the presence of medical supervision. However, if this had been the only difference between the scouts and the Manchester group, one would have expected a higher proportion of mild cases among the former. In fact, 5 of the 8 severe cases and only 1 of the 12 mild cases occurred at Torridon, and there is little doubt that the average attack was more severe in this group.

The quantity of pie eaten by the patients varied from 1 to 12 oz. Of the 49 cases in which information is available the average consumption was 4.9 oz. for mild cases, 4 oz. for moderate cases, and 4.1 oz. for severe cases.

The patients were aged 2½–65 years and of either sex. There was no obvious association between age and severity of attack within these limits.

INVESTIGATION OF OUTBREAK

On July 29 the bakery at which the pies had been made was inspected. It was a large modern plant employing about 100 persons. The standard of cleanliness was high and good sanitary accommodation was provided.

Preparation of Pies

The meat used for both pies and sausage rolls was supplied ready for use by a wholesale butcher. It had been minced, seasoned, and mixed with filler. A consignment of 80 lb. was received each Monday, Tuesday, Wednesday, and Thursday, and used the same day.

The pastry was made from flour, cooking fat, salt, and water. The dough was "blocked out" on a modern pie-making machine and the prepared meat was hand-

filled into the blocks by three female employees. The same machine was also used for "crimping" on the tops of the pies which were then placed in the oven for 25–30 minutes at 450–475°F. The gelatin was added after baking. Sheet gelatin was soaked in water, dissolved in fresh boiling water, and filled into the pies from a jug as soon as it had partially cooled. No eggs or egg products were used.

The pies were stored at room-temperature overnight and taken next morning to the twelve branches for sale. They were normally sold on the day of receipt and with few exceptions eaten on the same day.

Bacteriological Investigations at Bakery

None of the pie makers had recently had any gastrointestinal disturbance. One of the bakers was absent from work with diarrhoea and vomiting, but he had taken home some of the pies from the incriminated batch. He and his family had become ill after eating them.

The bakery was first visited on a Friday, when no pies were available for sampling. Owing to the Bank Holiday specimens of faeces from the three pie-makers were not obtained until Aug. 2. None of her family gave any history of gastro-enteritis, and their faeces were negative. The woman admitted that she was in the habit of eating pieces of raw meat while filling the pies.

Specimens of sheet gelatin, washings from the tin in which the gelatin was softened, and a mouse trapped in the bakery were examined bacteriologically with negative results. Specimens of six batches of pies made between Aug. 5 and 15 were bacteriologically negative.

Butcher's Shop

The meat used for the preparation of the pies consisted of five parts of hindquarter beef and one of fat pork. It had been received on July 23 and prepared two days later. Conditions at the shop were very unsatisfactory, and legal proceedings were successfully taken against the firm. It was impossible, however, to establish that the infection had been introduced from this source, or to find out whether meat from a single carcass had been used for the preparation of mince on successive days.

Samples of minced meat and of debris from the mincing machine and from the crevices of the cutting-up table on July 29 were negative bacteriologically. The faeces of all four employees and specimens of prepared pie meat collected on six subsequent occasions were also examined without result. No salmonellae were isolated from the only mouse trapped on the premises.

Other Investigations

On July 29 a divisional medical officer took possession of eighteen meat pies and seven sausage rolls which were on sale at one of the branches. These were stated to have been made on July 28—i.e. two days after the batch responsible for the outbreak—and subsequent investigations confirmed this. Two of the pies were sent to the laboratory and the rest stored in the basement of a town hall. A heavy growth of *S. abderdeen* was obtained from both of the pies. Unfortunately the rest of the batch could not be secured until Aug. 2, but in spite of having been five days at room temperature and become heavily contaminated with moulds, the organism was isolated from nine of the sixteen pies. None was obtained from any of the sausage rolls. It is therefore certain that batches of pies other than the one responsible for the outbreak were contaminated with *S. abderdeen*.

DISCUSSION

S. abderdeen was first described by Smith (1934) who isolated it from a sporadic case of mild gastro-enteritis.

in an infant. Subsequent records of its isolation from human sources are very scanty. The only published information for England and Wales is to be found in the table summarising the investigations of the late Dr W. M. Scott at the Ministry of Health laboratory (Wilson and Miles 1946). Dr G. S. Wilson and Dr Joan Taylor have kindly provided us with some further unpublished information. Scott's records contain no cases during the years 1923-38. Three "outbreaks" occurred in 1939, one consisting of a single fatal case of gastro enteritis in Liverpool. No information is available about the other two, but it is improbable that they involved more than a few people. The organism was isolated twice in 1940, once from a symptomless child, aged 4 years, living near Llandudno. There is no information about the source of the second culture. Since then the organism has been isolated on four occasions from single cases of gastro enteritis in adults at Oxford (1941), Northallerton (1946), Liverpool (1946), and Nottingham (1948).

We have been unable to find any records of human cases in other countries. There are none among the 3000 infections reported from the New York Salmonella Centre (Seligmann et al 1946) or among the 3016 identified by Edwards et al (1948) in the United States. The organism is not included in the large series reported in recent years from the Mediterranean (Bruner and Joyce 1947), India (Hayes and Freeman 1945), or the Pacific (Lindberg and Baylis 1946).

There are few records of the isolation of *S. aberdeen* from non human sources. Mallmann et al (1942) obtained it on two occasions in routine post mortem cultures from 294 chickens. Neither chicken had apparently died of salmonella infection. They state that this was the first time the organism had been isolated in the United States. It was encountered four times among 9315 salmonella cultures from non human sources examined by Edwards et al (1948) in fourteen years. All four isolations were from sporadic infections of chickens, and probably the two cultures of Mallmann et al (1942) are included in this total. *S. aberdeen* was also isolated from 'Ovomaltine' by Timmermann in Holland (Breed et al 1948). Despite the suggestion that the organism may be associated with poultry it is not included among the large series of salmonellae isolated from American spray dried egg (Medical Research Council 1946, Solowey et al 1947).

It is impossible to be sure how the infecting organism gained access to the food in the present outbreak. The transitory human excreter may have been responsible, but it is not certain that she was not herself infected by eating raw pie meat. The existence of one apparently unconnected case of infection in the area at the same time further complicates the picture without suggesting any alternative source of infection. Possibly the infection was derived from the pie meat. No source of infection was found at the butcher's shop, but a single carcass from an animal with salmonella infection may have been responsible. The few previous isolations of *S. aberdeen* in widely scattered parts of the world provide no clue to a possible reservoir of infection.

Previous evidence of the pathogenicity of *S. aberdeen* for man consisted of a few accounts of its isolation from sporadic cases of gastro enteritis and was therefore inconclusive. Also, Mallmann et al (1942) have reported failure to cause symptoms in rhesus monkeys by feeding large volumes of culture by stomach tube. The present outbreak establishes that under favourable conditions the organism can give rise to a typical severe gastro enteritis with septicaemia.

There was greater risk from eating large than small pies on the first day after manufacture, but by the second day the small pies seem to have become more capable of causing severe disease. Presumably a greater number of organisms survived the oven temperature

in the large pies than in the small, because of the relatively short period of heating. The sausage rolls seem to have been effectively sterilised. Experience with dried egg (Medical Research Council 1946) indicates that the minimal infecting dose of many salmonellae is very large. It is significant that no cases were detected as a result of eating a subsequent batch of infected pies, though the knowledge of the existence of an outbreak should have drawn attention to them.

Food poisoning outbreaks due to meat pies are common, and it is difficult to know how to prevent them. Hard filling is obviously undesirable, but its abolition would not guarantee safety. Any food containing raw meat which is not uniformly raised to a sterilising temperature is potentially dangerous. It is only necessary for a few pathogenic organisms to survive, because there is usually ample opportunity for them to multiply before the food is eaten. It would be reasonable to insist that the meat be thoroughly cooked before being filled mechanically into the pies.

SUMMARY

An outbreak of food poisoning due to eating meat pies infected with *Salmonella aberdeen* is described.

The clinical condition was a short pyrexia, usually but not always accompanied by diarrhoea and vomiting. Several of the cases were severe, and one patient underwent appendicectomy in the acute stage of the illness.

The investigation of the outbreak did not reveal the ultimate source of the infection.

Methods of reducing the risk of salmonella infection from meat pies are discussed.

We wish to thank Dr G. S. Wilson and Dr Joan Taylor for unpublished information and the latter for confirming the identity of representative strains of *S. aberdeen*, Dr H. Macpherson for allowing us to make use of his bacteriological findings on the cases in Invergordon Isolation Hospital. Drs D. G. Anderson, A. Telford Burn, J. Landless Horne, D. Longbottom, C. H. T. Wade, and R. Q. O. Wheeler for clinical or epidemiological information, and Special Sanitary Inspector A. W. James, of the Manchester Public Health Department, for his help.

Measles

The biennial peak in notifications of measles is due to occur in the early months of next year. Already the number of cases has reached epidemic proportions. During the past two months notifications have increased at the rate of one thousand a week, for the week ended Dec 9 the total was 12,323. This is a steep increase than that in the last epidemic period two years ago, but in 1948 the build up in the country as a whole during the late summer and autumn was more substantial.

The incidence this last summer was most intense in the Potteries and the North-East, but these districts have been relatively free in recent weeks. Now the majority of cases are being notified in the counties around London in Lancashire, and in Yorkshire (East and West Ridings). Of the county boroughs, Kingston upon Hull has been affected considerably more than any other, in November almost 3000 cases were notified from this source. The infection is reported to be comparatively mild.

Parliament

Minister on Registrars

IN the House of Commons on Dec 15, Sir HUGH REES-TOOTH raised the question of hospital registrars' connection with the Ministry of Health's recent circular. Mr FRED MESSER urged the Minister to consult the teaching hospitals and regional boards before putting the circular into operation.

Mr ANEIRIN BEVAN said that a large number of doctors had returned from the Services anxious to be named as consultants, and many more posts had been provided than was reasonable. All that the Ministry was trying to do was to relate the number of registrars aiming to be consultants to the number of consultant posts that might be available. Obviously it was not going to enlarge the number of specialist posts until there were the hospitals with the work. The number of names was now nearly 3000. In 1938 the number was of more than 750. Even the proposed new total of 700 was nearly $2\frac{1}{2}$ times the pre-war figure. There had been a good deal of misunderstanding about this matter, and a good deal of resistance much of it from outside the medical profession. It must not be assumed that complete harmony existed between the specialist and the general practitioner, on the contrary, there was often a considerable amount of friction.

In these days when the specialties were tending to proliferate, it was essential that some of the more substantial branches should have a more adequate number of registrars, and that some of the new specialties should not get more and some of the older ones not enough.

Dr CHARLES HILL asked if the Minister would invite the regional hospital boards to comment on the new establishments. Mr BEVAN replied "Certainly." The main purpose of the circular was to try in future to have sufficient numbers to do the normal work of the hospitals and then to have a number of registrars who were training to be consultants. In the past these categories had been blurred, and because of this there had been a tendency to enlarge the category of registrars. He was certain that this step would be in the interests of all concerned.

Medicine and the Law

Accident due to Lighting Failure

A RECENT fatality at an Essex hospital, the subject of an inquest at Chelmsford, is a warning to hospital authorities not to neglect preparation for the consequences of a temporary lighting failure.

An infant boy, 4 days old, was in an oxygen tent. His condition and that of his twin sister caused considerable anxiety. Suddenly the lights in the ward went out and the ward sister struck a match in order to see to her two little patients. The tent went up in flames. She turned off the oxygen and took off the tent in order to get to the baby, whom she took to another ward. She extinguished the flames. There was evidence that she had had plenty of experience with oxygen tents but there was no torch available and she had not been told where any portable lighting apparatus was kept.

A verdict of accidental death was recorded. The coroner expressed his strong opinion that the accident was not due to ignorance or lack of knowledge but to the sister's preoccupation with her patients' safety. To strike a match in the darkness was perhaps an instinctive act, one done in haste with the best intentions and without thought of the consequence. The coroner suggested that the hospital authorities should inquire into their emergency arrangements forthwith so that such an accident should not recur.

Hospital managements everywhere will wish to satisfy themselves that the danger is appreciated.

In England Now

A Running Commentary by Peripatetic Correspondents

HE wasted no time on the platitudes commonly expected on a first visit. I had a quick impression of cherubic pink cheeks, a magnificent snow-white beard and morning dress (unusual in my practice), but I had no time for a further survey before he dropped heavily into the patients' chair and announced, with a strong Continental accent, "You must help me. I am too thick."

I'm used to patients who come to be cured of obesity, but they are generally women and most of them are under sixty, whereas this man must have been at least seventy. But it wasn't for me to dissuade him from regularising his waistline, which was undoubtedly too expansive so I took up my pen and prepared to take a history. It wasn't easy going, apart from the language difficulty there seemed to be some misapprehension in the old fellow's mind that we'd met before and that I must know everything about him. I was convinced that I'd never treated him before though when he first came in I had felt that I'd seen him somewhere in different surroundings and totally different clothes.

Anyway, after a quarter of an hour one thing had clearly emerged. It wasn't for his looks that he wanted to lose weight but because his girth was interfering with his job. "Still working?" I inquired, surprised at the staving powers of some of our seniors. He shot me a glance of as near shocked contempt as that benign cheerful face could express. "Every year I work," he said with dignity. "Last year I was also thick though not as now and it was a very squeeze, but this year I am already so thick I have fear I shall not get through. So I come to you in good time that you may make smaller before my work begins." Ah! Seasonal work, I thought. But I ventured to hint that perhaps at his age (he was obviously comfortably off) it wasn't necessary to work at all. This time I got a really scorching glance from his surprisingly youthful blue eyes. But he calmed down again, and thanked me politely for the usual advice I gave him on diet and exercises.

"It is not chust for myself," he said, as he rose with difficulty from the comfortable chair I provide for my patients. "It is for my staff also. If I am bigger get-they cannot any longer pull me. At any moment they may—how do you say?—strike. It is heavy for them with me, and all the extra loads, you know." "Have you a large staff?" I inquired politely. "Six or eight always some extras in the stables," he replied. Now at last I understood. Unlikely as it seemed at such an age my patient was connected with a riding school and still rode occasionally for demonstration or teaching purposes. He might even be attached to a circus—that would explain the seasonal aspect of his job.

"Ah," I said knowingly, as we shook hands at the door. "I see now. You work with horses?" "No," he replied as he turned to go. "You have forgotten, my child. Reindeer."

* * *

I have been in and out of hospitals man and boy, as patient student and doctor for the past fifteen years, and I must regretfully report that many conditions have not improved in the least. The old adage about a doctor having a dose of his own medicine applies with equal truth to the nursing staff. The obvious relish with which a nurse, when about to give an intramuscular injection of the latest wonder drug "wipes the blunt end of a bent and rusty needle with a piece of cotton-wool dripping with ether meth or alcohol, leaving a little tuft of fibres on the barbed end, has to be seen to be appreciated. She then orders the victim to "roll over," bathes his skin with alcohol and, with a practised, but unsteady hand, jabs towards his sciatic nerve. The needle having entered at a tangent is barely intramuscular at its barbed end, but, not bothering to pull back the plunger to find out how much bleeding is going on she presses home the plunger with a gay abandon acquired through years of malpractice thereby forcing the drug out at the bevel of the badly fitting

needle and forcing air into the patient. She then gives the skin another flooding with alcohol and goes on her way rejoicing, leaving the patient who knows no better to blame the new antibiotic for the pain of his intracuticular injection of alcohol and to boast later to his relations that he "bruises so easily."

Medicines are given out, b d or q d s, always p c, and nothing will make a ward sister give them a c—unless the patient is a "gastric," when he will be given his "trisilicate" with one hand and his milk pudding with the other. If any patient is rash enough to say "no" to his evening catechism he is quickly given mist alba or tabs cascara. How much simpler it would be if due allowance were made for the hospital diet, consisting of white bread and potatoes, with very very rarely any fresh lettuce or properly cooked cabbage and seldom any fruit. Even the most active of guts are soon undermined by such food, especially when it is supported by tabs A P C for this, that, and the other pain, headache, or malaise, not to mention the morphine derivatives, and routine dosing with "ferrous sulph." And how many hospitals have a commode? If every house governor, every matron, every member of a management committee were made to wait in bed, as patients, until their neighbour found time to wheel them to the toilet, commodes would be provided as quick as the proverbial lightning.

Do physicians always realise, when they study the temperature chart, that "morning temps" are taken any time between 5 and 7.45, and that a thermometer is seldom left in the mouth for more than the "half-minute"? Nobody ever bothers about the effect of Summer Time on the time of the patient's peak temperature, and to persuade the nurses to recognise Double Summer Time in anything except hours off duty would be as great a waste of time as counting the pulse for a quarter of a minute, or with the aid of an hour-glass.

Despite all the errors in their teaching, I have met only one nurse who made me mad—she simply could not do anything quietly and loved to exercise her strident voice—and there is no more sympathetic and welcome character than the night nurse who optimistically rubs a mixture of water, alcohol, powder, and soap into your gluteal muscles at three in the morning.

* * *

Reassurance, I was always told, is very important in cardiology. When a man who had had very severe pain in his chest told me that it was only a bad spell of his cardiac neurosis, diagnosed eight years before at my old teaching hospital, I began to see what could be done in this line. An electrocardiogram with clear evidence of myocardial infarction showed that his condition had altered considerably in the interval, but his confidence in the original diagnosis was unshaken. I mentioned this to a colleague and heard an even better example. He was working in a hospital near the terminus of an airline, when one day an American civilian was brought in from an aircraft somewhat collapsed and with a pain in his chest. Between gasps he was understood to say "This is only my cardiac neurosis. Dr X (a world famous cardiologist) has been treating me for it for years." Thereupon, ECGs were taken, transatlantic telephones were called into play, and eventually the patient was persuaded to spend the necessary time in bed for his coronary collaterals to develop. All this leaves me enviously feeling that I must polish up my reassurance.

* * *

Have you come across one of those unfortunate surgeons who suffer from hyperactivity of the nasal mucosa? He usually wears his mask so that its upper margin lies immediately below his nose. For operations lasting up to half an hour a series of powerful sniffs will successfully control the ever present menace of a drop separating itself from its host, but for longer procedures the anaesthetist or a nurse has to wield a piece of gauze, usually just in the nick of time. I was pondering on this weighty problem during a lengthy operation when the answer came to me in a flash—why not Tudor Edwards spectacles fitted with continuous suction?

Letters to the Editor

THE CHANGING FACE OF SURGERY

SIR,—The address by Sir Cecil Wakeley at the Westminster Hospital Medical School, published in your issue of Dec 9, contains some observations on specialisation in surgery which I feel must be challenged. Sir Cecil repeats the usual arguments of the general surgeon against specialisation when he says "Such a state of affairs is bad for teaching and makes for little progress. There is a tendency to view a patient with ultra specialist eyes and only see a minute part of the anatomy instead of considering the patient as a whole." He further states "It is important that surgeons on the staff of teaching hospitals should remain general surgeons, but it does not matter if they have a hobby—for instance gastric surgery, thyroid surgery, or urological surgery."

As the surgeon in charge of a urological department in a teaching hospital, may I point out the vast difference in "making a hobby" of gastric or thyroid surgery and of urological surgery. In the first two examples a single organ is being dealt with, in urological surgery a whole system. I am writing this letter a few hours after making a round of my department. The range of conditions dealt with can be gauged from the following examples of disorders in patients at present occupying the beds.

Renal and ureteric calculi (treated by pyelolithotomy, nephrolithotomy, ureterolithotomy, or nephrectomy), renal tumour (nephrectomy), hydronephrosis (cases which have had conservative plastic procedures), stress incontinence, urethral carcinoma, epispadias, prostatic obstructions, benign and malignant (treated by open operation or per urethral resection), and bladder carcinomata (treated by diathermy, radium, partial cystectomy, or total cystectomy). This list is incomplete and takes no account of the preliminary specialised diagnostic procedures, carried out for the most part before the patients were admitted to hospital, but it will suffice to show that something rather more than dilettantism is required of those who would undertake urological surgery. Furthermore, can it be seriously suggested that in a urological department there would be less tendency to consider "the patient as a whole" than there would be if these patients were interspersed amongst others suffering from haemorrhoids, hernias, varicose veins, and other more major surgical lesions? On the contrary the urologist with his paramount responsibility for prostatic disorders and the cardiovascular, renal, diabetic, and pulmonary complications commonly associated with them is particularly aware of the need for general assessment. Many housemen have spoken to me of the value of the "medical" experience they have had while occupying the resident's post in the urological department.

With regard to the remark that specialisation makes for little progress, surely the opposite is the case. Certainly in the past thirty years, during which urology has been finding its place as a recognised specialty, the phenomenal progress in the subject has been due to outstanding contributions by urological specialists and not general surgeons. Thus, Hugh Young devised the earliest prostatic punch, and Edwin Beer showed how to destroy a growth in the bladder by electric desiccation. Stern and McCarthy devised the resectoscope, and Thomson Walker and Harris advanced the technique of transvesical prostatectomy, and Zwick, working with von Lichtenberg in his urological clinic, gave us intravenous pyelography. The application by the urologist, Huggins, of endocrine therapy to the treatment of prostatic cancer has proved an outstanding contribution to medical science, and the retropubic extravesical method of prostatectomy by Millin a brilliant contribution to the surgery of the prostate. I know of no comparable presentments to urological progress emanating from general surgeons.

With regard to the problem of teaching the undergraduate must of course receive instruction in urology as part of his surgical course. If as is advocated by Sir Cecil, one of the general surgeons in the teaching hospital makes urology his particular sphere, his wards are likely to have a concentration of urological cases. Unless, therefore, a system prevails of all students rotating in turn round all the surgical firms—certainly an impossible arrangement in most provincial medical schools, served as they are by several hospitals each with a number of surgical units—only those attending the ward especially concerned with the urological patients will receive adequate instruction in the subject. I suggest that the teaching should be integrated with the general surgical course but that it should be given by the specialist staff, who have at their disposal not only the necessary teaching material but also the outpatient, diagnostic and ward facilities for displaying it.

I would affirm that the primary function of a hospital is to arrange for the optimum treatment of its patients and this obligation applies as much to the teaching as to the non-teaching hospital. Because of the limited number of urological departments in Great Britain, particularly in the teaching hospitals, a considerable proportion of urological surgery is still carried out in general surgical units. It would be difficult to contend that the standard of their urological work is comparable to that of the special departments, equipped and staffed for the purpose, though there are some outstanding exceptions to this general rule. The need for urological departments has long been recognised on the European continent. Many of the larger hospitals in Paris have units of over 50 beds, and in the 1000 bed hospital of the Liver medical school the urological unit has 110 beds. In the U.S.A. no hospital of standing appears to be without its urological department, many housed and equipped in a manner to be expected only in that country. Let us here not attempt to put back the clock.

I feel strongly for the prestige of urology. My own hospital was early in recognising the needs of the specialist and generous in responding to its claims. I am anxious to see the same conditions prevailing elsewhere.

Glasgow

ARTHUR JACOBS

REGISTRARS

SIR.—One of the more perplexing aspects of this affair has been the method of publication of the Ministry of Health's circular E.H.B. 50/106. When it appeared most people, I believe, thought it had been produced without prior consultation with the profession. That seemed perhaps its worst feature. We are now told by the Ministry that it was 'issued after full consultation with the profession's representatives', and we learn that, though not an "agreed" document, its contents have, in fact, been the subject of discussions between the Ministry and the Joint Committee for some time.²

It is reasonable to ask in what capacity the Joint Committee stood to the Ministry in these discussions. Was it acting as the general representative and mouthpiece of all consultants and registrars, or was it in the role of Whitley Council for Consultants and Specialists (which I thought was now its main, if not its only, function)? It seems doubtful having regard to the purpose of Whitley machinery, whether the subject of registrar establishments is a proper one to be referred to this committee. Whichever was the case it is difficult to understand why there was no consultation at lower levels. For several months discussions have been going on between the Ministry and our representatives concerning matters which closely affect the professional life of all

consultants and registrars, and most of those concerned have had no knowledge of them, and played no part in them.

It has been suggested, although it seems incredible, that the Ministry asked the Joint Committee to keep the discussions confidential. If this was so, it appears that the proper course would have been for the Joint Committee to refuse to take part in them as being unwilling to commit their colleagues on such an important issue without consultation with all concerned. There is no point in keeping matters of this kind confidential, and if there is pressure from any quarter to do this it should be resisted by the profession.

Evidently the discussions were fruitless and it appears that the Ministry decided to fly a kite with E.H.B. 50/106. It has now, in the end, become necessary to consult all levels of consultants and registrars. All kinds of meetings have had to be called, often at short notice, and information on hospital work and statistics hurriedly gathered and sent to bodies such as regional hospital boards, which have become involved in unwanted labour collecting the facts and bringing forward proposals for the continuation of the hospital services about which they are naturally anxious. Indignation and perplexity have been engendered at all levels, neither state of mind being conducive to balanced and thoughtful judgment. If this particular problem had originally been passed down to the peripheral hospitals and consultants the necessary discussions could have taken place over a reasonable period of time. This would have resulted in consultants and registrars being fully informed of the points at issue, and all would have had ample opportunity to state their case and make constructive proposals before the Ministry began to formulate policy.

This is not the first time the hospital service has been disturbed—we went through a somewhat similar experience when the post-war registrar scheme was wound up. In the present instance the Ministry itself cannot escape blame for the method of publication of this fateful document but whatever else comes out of this affair it is permissible to make the point that hospital medical staff need adequate consultative machinery at all levels up to the Ministry if the hospital service is to run smoothly and with satisfaction to the doctors who work in it. The particular form this might take should become a subject for discussion at once. It is doubtful if the Whitley machinery is suitable except for its already defined purposes. The B.M.A. Central and Regional Consultants and Specialists Committees might be suitable for the work with stronger regional representation on the central committee. It would be important for the committee which finally dealt with the Ministry to be as representative of all groups of hospital doctors as possible, and for the machinery really to be used for consultation downwards. In this way the top committee would voice the views of those whom it represented, and by doing so would not only bring satisfaction but strengthen its position with the Ministry. An alternative arrangement would be a system of consultative machinery within the hospital service itself. The chief merit of any scheme should be the adequate inclusion, at all levels, of opinion representative of area hospitals and smaller non-teaching hospitals. The present difficulty is in part due to the overweighing of teaching-hospital opinion on the Joint Committee. The time has come when the views of those working at hospitals which perform the major part of the clinical work of the country should be well represented in discussions with the Ministry.

To return to the particular problem of the registrars, it is a fact that the circular in question has startled the profession. Although its extreme proposals cannot be taken seriously its appearance has had an unsettling effect on the service. Registrars' sense of security has been shaken. Consultants are concerned as to how they

¹ *Lancet* Dec. 9 1950 p 775

² *Brit. med. J.* suppl., Dec. 2 1950 p 225

are to carry on their hospital work, and the future of the hospital service seems suddenly darkened. Much is at stake, not least the maintenance of the standard of work in many hospitals where adequate staff (consultant and registrar) has only recently been appointed for the first time. It is perfectly clear that if registrars are to go, to maintain quality and quantity of work others of equal ability must take their place. Discussion chiefly centres on how this shall be done. You were right to have doubts about your "second premise" in your leading article of Dec 9, but the question of a junior grade of consultant is not easy to settle. I suggest that a very strong case indeed can be made out for a *moderate* increase in the number of *full* consultant posts *now*. In addition, a number of "assistant" or "junior" consultant posts could be made, as a temporary measure, in suitable hospitals. The particular merit of these two suggestions is that most of the senior registrars who are now fully trained could be kept in hospital work, if necessary for some years, until promotion was possible to the full grade, and in this way the work of the service would be unimpaired. If the number of new consultant posts of all kinds was less than the present number of registrars (and it is generally conceded that this must be so) there should be no financial drawback to this arrangement. Something must be done to preserve the present standards of the hospital service and to prevent hardship among a group of able, hard working, and admirable colleagues—our registrars. It has lately been proposed that consultants might make a financial contribution to ease the difficulty.³ This is very reasonable. I am sure I am not the only relatively young consultant who would be prepared, for instance, to go up the incremental ladder more slowly than at the present prescribed rate. But more might be needed, and consultants may have to be prepared for some sacrifice if the hospital service and the present registrars are not to suffer.

One more point. The importance to the hospital service of the work of registrars has been stressed by you and many others, but it must not be forgotten that registrars are in training for something higher. Their number is bound to be reduced, but if too many are taken from area hospitals—even if they are replaced by other doctors—the service will still suffer because the training to be had at an adequately staffed and equipped area hospital is of value to the man training to be a consultant, and there can be no doubt that the presence of such trainees is a stimulus to the senior staff at any hospital.

West Middlesex Hospital, Isleworth

N F COCHRAN

SIR,—The Chancellor of the Exchequer has placed a ceiling on health service expenditure which, judging by other calls on national resources and particularly those of rearmament, seems unlikely to be raised in the foreseeable future. That being so, it is surely time that the Minister and his advisers decided how the available money should be spent to the best advantage, as is done in any other concern not blessed with unlimited funds.

It is, I think, evident that a properly run hospital service is much more important to the community than the free supply of dentures, wigs, corsets, spectacles, and so on, to all and sundry. For such a service an adequate number of specialists is essential, and on the Ministry's own showing the number at present employed is only about 65% of what it regards as the optimum. The work in the hospitals of this country which cannot be undertaken by the consultants—many of whom, incidentally, are working for many hours more than their contracts call for—is undertaken by registrars, and should their numbers be reduced, as is proposed, the work of the hospitals will suffer accordingly.

One need not dwell on the cynicism with which it is suggested that these men should be thrown into the discard, or at best used to obtain specialist services at cut rates in the Armed Forces, but it would be well for the Minister and his advisers to ponder whether their long training and skilled services are not of greater value to the community than the free supply of the various appliances I have mentioned. I would suggest that it would be no great hardship if such facilities were limited to certain well defined groups, such as school children and old age pensioners, while others paid for them in cash, thus freeing money for more important aspects of the health services.

Great Clifton, Cumberland.

IAN MACKENZIE

SIR,—The Ministry of Health's circular on registrar appointments has caused anxiety and disquiet to senior registrars and registrars, mainly because of the insecurity which its terms imply. From the apparent security of their permanent appointments consultants should cover to the Ministry their grave concern at the callous indifference shown by the suggestions contained in the document.

Especially affected are those relatively senior doctors who served throughout the war and who, mainly through encouragement by the Ministry and by post war training schemes, have restricted their activities to hospital appointments with the intention of filling the consultant vacancies which they were led to believe would abound. Registrars (many in their late thirties or early forties) have had these promises rudely broken, and they can foresee no security in any branch of medicine. The most essential immediate step is to persuade the Ministry to freeze all registrar appointments until satisfactory plans have been made for hospital establishments.

For generations hospital staffing schemes have distinguished between junior and senior appointments, but, largely through the opposition of consultants, such was the lack of foresight in the grading of the present National Health scheme that a gap was at once created through the refusal to recognise this distinction between senior and junior consultants. It is likely that this anxiety and difficulty with regard to registrars would not have arisen had this gap not been created.

The remedy would appear to be the formation of a grade of junior or assistant consultant. Consultants must be persuaded, as must the Ministry, that such a grade is essential if hospitals are to be adequately staffed by clinicians fit to take the responsibility. Without such a grade consultants will be overwhelmed by the volume of work. No one in any specialty is worthy of a consultant appointment with less than ten years' experience, and appointments to the consultant grade should be made from the grade of junior consultant when the necessary further experience has been obtained. Senior registrars who entered this junior grade would know that only a proportion of them would ultimately reach consultant grade, but the salary in the lower grade should be big enough to assure a reasonable livelihood. These junior consultant appointments should be permanent, to provide some sense of security, and those entering the hospital service in the future should have some idea of the number of permanent appointments available. Junior consultant might receive a salary of £1400 rising by £50 per annum to £2000, and after 15 years' service rising by further annual increments of £50 to £2200. They should have a separate scale of salaries and not that of consultants; otherwise there will be added further anomalies to those existing today owing to the fatuity of paying all consultants alike, irrespective of the specialty, the quality, and/or quantity of work, and the responsibility of the appointment. Registrars who have already proved themselves of value to the hospital service should be

omoted where warranted to this grade in the hospitals where their worth is known

The major proportion of work in a general hospital is general (often humdrum) medicine and surgery, and the suggestion for giving greater prominence and attraction to minor specialties, where vacancies are said to be numerous, should be deprecated. Applicants for these minor specialties should graduate through the junior consultant grade rather than be given consultant rank at too early an age. The solution will not be found by appointing more consultants to individual hospitals, as this would mean more consultants doing less, and add to the difficulties of allotting beds or wards and operating and outpatient sessions where accommodation did not exist.

It is "assistants" (call them what you will) that are wanted. More consultants will require more assistants, and it is the latter who will be scarce if these cuts are imposed.

Today too much emphasis is placed on teaching, and teaching hospitals (valuable though they be) should not be given an excessive quota of registrars. Moreover, teaching hospitals should not dominate decisions on new appointments to non-teaching hospitals.

Many hospitals today are grossly overstaffed in over all establishment, and where lavish staffing has been encouraged establishments should be pruned and brought within reasonable limits, beyond which no future reduction should be made.

Among the different staffs in hospitals—as in every profession and trade in the country—the waning capacity for work should be increased, otherwise, by lagging behind, the hospital service may fall into disrepute. In such directions, and too many others in the hospital service, the Ministry may find the economies for which it appears to be looking.

Hillingdon Hospital
Uxbridge Middlesex

W ARKLEY STEEL

SIR,—As a general practitioner, I wish to join the registrars in their protest against the proposed cut in their numbers.

Out of interest and prestige general practitioners could take clinical assistantships, but they could not profess to replace the registrars. Unless the number of consultants is increased or the number of registrars kept up, the volume of medical work in hospitals will inevitably fall.

What of our own future? Reduced lists without an increased capitation rate become a possibility if 1100 partly trained specialists are wastefully thrown into the general practitioner market. We must see the mutual relation of our problems.

Abersychan
near Pontypool Monmouthshire

A S JARMAN

SIR,—I agree with Dr MacWilliam¹ that merit awards, which have caused so much distaste and unrest among consultants, might be better employed in preserving the 1100 registrars who are to be summarily dismissed.

Registrars have always had a long path to tread, and few reached staff appointments under 35 or 40 years, many fell by the wayside and discreetly moved away into general practice which afforded them some use of the specialty they had previously aimed at making their life's work. No registrar, therefore, worthy of his salt minds the risks of defeat, they have always been present. But a mass dismissal is a different matter. General practice cannot absorb so many embryo specialists at once, so that many "sacked" registrars will be out of work for a long time. I hope they are eligible for unemployment benefit.

The peremptory Ministry of Health memorandum, with its offensive paragraph 12, is now stated to have been discussed before publication "with the profession's representatives." I feel that many of us would dearly like to know who (if any) of our colleagues agreed to this treacherous document.

The consultants must stand by their junior colleagues who are responsible for such a great part of hospital work, for without them the hospitals will surely founder, and I for one offer what services I can give to the registrar body. Let my fellow consultants realise that if they permit this slaughter of their junior colleagues, without making every effort to stop it, then the way is open for future attacks on themselves.

Wolverhampton

E G DOLTON

SIR,—Whilst agreeing with the suggestion, in your leading article of Dec 9, that "when hospital building is approaching a standstill, it is unrealistic to suppose that the establishment of consultants can soon be brought up to the optimum contemplated in the Ministry's *Development of the Consultant Services*," I cannot see reason to suppose that no increase in the establishment is possible. The Ministry's memorandum envisages no increase, yet the need exists, and it is partly masked by the large number of registrars, many of whom are doing work which should properly be done by consultants. An immediate increase of 500 consultants is necessary, is possible within the present limits of accommodation, and would avoid the registrar problem which threatens.

Other measures are also necessary, including (1) a decrease in the rate of recruitment of registrars, (2) a decrease in the number of registrars, to be achieved by not reappointing those thought unlikely to reach the top grades in the profession, (3) a restriction preventing consultants accepting more than eleven sessions (many have sixteen or more), and (4) possibly an increase in the establishment of posts of the S.H.M.O. type, as you suggest.

By these means the standard of medical service will not be lowered, the ability of the best of the present registrars will not be wasted, and hardship will be minimised. There would not be need to dismiss an excessive number of registrars, and those dismissed would on the whole be the less able ones. To dismiss 1100 registrars regardless of ability is unjust and not in the best interests of the service. And, most important, there will never again exist a pool of trained men, such as at present, from which to expand the consultant service.

Middlesex Hospital London W 1

CECIL McIVER

SIR,—The registrar problem is the concern of everyone at the present moment. Most of us in the senior consultant ranks have one or two of these younger men working with us, and we are trying to do everything in our power to ensure that they shall retain that place in the hospital service which they have already worthily earned.

Yet I do not think that Dr Ffrangcon Roberts, in his letter of Dec 9, strikes just the right note in putting forward his particular solution of the problem. Practising north of the border, one may be speaking from insufficient knowledge of conditions in the south, but the picture painted by Dr Roberts of the registrars doing a great deal of the most difficult operative work and much of the outpatient consultation work, and providing the means whereby the consultants are enabled to do private practice, seems overdrawn.

In the Scottish teaching hospitals with which I am familiar, all important and difficult operative work and all outpatient consultation work is done by consultants. Registrars do a proportion of the routine operative work.

¹ MacWilliam H H *Brit med J* Dec. 9 1950 p 1329

but only under supervision, and they are never in sole charge of a unit. They work under definite limitations laid down not only by the chief but also by the hospital management committee. They do much useful work, but they are not the key men in the hospital, nor are their services the means whereby consultants are allowed extra time for private practice.

Doubtless Dr Ffrangcon Roberts speaks from conditions which he has personally observed, but he makes no reservations, geographical or otherwise, and it would be a pity if the picture he has drawn were to be regarded both at home and abroad as the true over all one. Perhaps there is virtue in his solution of the registrar problem. My criticism is only of the statements he has made to advance it. Incidentally, Dr Roberts has solved another problem for us—namely, where private practice has disappeared in recent times. Apparently it has all centred round the Cambridge area.

Glasgow

ROBERT MAILER

SUPPURATIVE PNEUMONIA

SIR,—The very interesting lectures by Dr Nicholson, published in your issues of Nov 18 and 25, prompt me to report a case of chronic lung abscess following staphylococcal pneumonia without signs or symptoms and with unusual radiographic appearance.

An upholsterer, aged 51, was admitted to St Nicholas' Hospital towards the end of January this year with right lower lobe pneumonia. His white blood cell count was 17,100 per c mm., 15,730 of which were polymorphs, and the sputum contained coagulase positive *Staphylococcus pyogenes*, insensitive to penicillin. He responded well to a course of sulphamezathine and streptomycin, and the signs in the chest gradually disappeared.

To my surprise routine radiological examination of the chest during convalescence showed a large rounded opacity in the right lower lobe (see figure). Bronchoscopy, blood count, blood sedimentation rate, blood Wassermann and Kahn reactions, Casoni test, and repeated sputum examination gave negative results, and by early February he was up and about in the ward and began to put on weight. As the opacity persisted he was referred to a chest unit early in April. It was thought that the mass in the right lower chest was a coincidental finding unrelated to the staphylococcal pneumonia, and the possibility of gastrogenous cyst or neurofibroma was considered.

The patient continued to remain well, without any signs in the chest, and serial radiographs from April to August showed gradual diminution in the area of opacity, a bronchogram suggested that the cause was extrapulmonary. In August the patient was transferred to the same chest unit, where a right lower lobectomy was performed. The pathologist's report on the specimen was as follows: "Specimen consisted of the whole right lower lobe. Beneath a plaque of pleural thickening was a cavity with thick fibrous tissue

walls, lined by granulation tissue. No evidence of neoplasia or tuberculosis microscopically."

Postoperative recovery was uneventful and the patient remains well.

ST PAUL'S GRAY APPOINTMENTS

SIR,—The two paragraphs which Miss Hornsby Smith quotes from *Hansard* in her letter of Dec. 9 contain several inaccuracies and show how badly informed she was when she made her statement in the House of Commons.

Miss Hornsby Smith writes that she never alleged that the L C C had appointed us to our practices. According to *Hansard* she actually said "I am raising on the Adjournment the method of appointing doctors to the London County Council estate area known as St Paul's Gray the L C C by deciding which doctors should be allocated a house from which they can practice are choosing the doctors on this estate." Later, in reply to Members who found it as difficult as we do to know what was her complaint, she stated "I made the accusation against the London County Council that is the purpose of raising the matter on the Adjournment."

Since that was her purpose, it is surprising that she mentioned the names of two doctors who have no connection with the L C C, and failed to mention other doctors who have also started practising in the area at of whose existence she must surely have learned during her discussion with "the secretary of the local Medical Practices Committee" (presumably she meant the secretary of the Local Medical Committee). Referring to us Miss Hornsby Smith said "I first had shoals protests about these gentlemen and that gave rise to an investigating [the matter]." We wonder why she has not disclosed from whom she received these shoals.

REVOLT AT KINGSTON

SIR,—I was glad to see that Dr Morgan had corrected (Dec 9) Dr Stark Murray's distorted version (Nov 2) of the happenings at Kingston.

Dr Murray's antagonism to general practitioner hospitals appears to render him incapable of putting the facts fairly and honestly. A good general practitioner service is as necessary for the community as any other part of the health service, and should be an integral part of it, co-ordinated, as far as possible, with the hospital and public health service. It has long been recognised that the general practitioner will achieve a high standard of work if he has access to hospital. Lord Webb-Johnson, president of the Royal Society of Medicine, said on Nov 22 that all engaged in the practice of medicine would deplore the present tendency whereby general practitioners were deprived of opportunities which should be theirs at local hospitals.

But we do not want the general practitioner hospital as visualised, in his ignorance, by Dr Murray. We want to retain the type of general practitioner hospital exemplified by the Kingston Victoria and Surbiton hospitals where the practitioner works in conjunction with a consultant and specialist staff, and is able to learn what advances are being made, see procedures carried out, and discuss cases with them. In short, a hospital which will prevent him from being left in medical isolation and help him keep his standard of medicine, and so make him more useful to the community. The

A anteroposterior view and B lateral view, showing round mass in the lower zone of the right lung

called "revolt at Kingston" has aroused the interest of general practitioners all over the country, because they know the Kingston Victoria Hospital is fighting for an ideal, and they are all waiting to see whether the Minister of Health is going to stand by his recommendations on the matter of general practitioner hospitals which he issued last year to regional boards, or whether it will continue to let the matter be settled by "planners" who have no knowledge of the aims and ideals of general practitioners.

Gynaecological cases are not the only ones for which beds are urgently needed. This manipulation of beds in the proposed scheme is only robbing Peter to pay Paul, and it is open to question whether this is for the benefit of the community.

Tolworth, Surbiton, Surrey

FLAME PHOTOMETRY

SIR,—The article by Dr Spencer in your issue of Nov 25 will have left many readers with the confused feeling that flame photometry, though doubtless a very convenient and rapid method of estimating certain electrolytes, is hardly suitable for use in a routine laboratory, owing to the complexity of the apparatus and the numerous possible sources of error. In fact, however, for ordinary clinical purposes, flame photometry can be carried out with quite simple equipment which can be designed to eliminate many of the sources of error mentioned by Dr Spencer, while some of the other sources are in fact of very little real significance. For instance, Dr Spencer's figures for the effect of urea show that the amount present in undiluted urine would produce less than 2% error, and urine is usually diluted 1/100 before use.

The main means by which a flame photometer can be simplified and rendered less liable to error is by modifying the design of the atomiser and burner. Dr Spencer is quite correct in saying that the design of the atomiser is critical, but his brief account and illustration of various possible types does not shed much light on the subject. Essentially, atomisation is produced by feeding liquid into a high velocity gas stream, and, other things being equal, the higher the velocity of the gas stream the finer the droplets produced, and the larger the proportion of the liquid therefore made available for feeding into the flame.

The use of coal gas is unsatisfactory for two reasons: if taken direct from the main, the pressure is liable to sudden small variations which make direct photometry, as Dr Spencer rightly says, unreliable (pressure stabilising devices are available but they increase the complexity of the apparatus); secondly, the pressure of the gas is insufficient to produce atomisation, and compressed air must therefore be used for the purpose. Most institutions where compressed air is available on the bench employ a pressure of between 5 and 10 lb per sq in., which does not produce efficient atomisation. It is therefore necessary to use either a blower, which is usually noisy, or a cylinder of compressed air, when the stability of the photometer depends on the efficiency of the reducing valve employed. Both these disadvantages can be overcome, and the atomiser and burner combined into a single unit, by using a gas such as butane, which can be stored as a liquid with a vapour-pressure of 30 lb per sq in. at room temperature. This pressure is amply sufficient to give a gas velocity which will produce efficient atomisation and it will vary only slowly with changes of temperature of the cylinder. The atomiser can be made an integral part of the burner, and the jet will then draw in sufficient air for complete combustion.

Another disadvantage of the system suggested by Dr Spencer is that it not only uses solution at an excessive

rate, but also wastes it, in that once the funnel is filled it must be emptied before the solution can be changed. An atomiser such as that shown in his fig. 2a can be designed to be as efficient as any other, and if the dead space is kept small no solution will be wasted. By using a single gas at a practically constant pressure not liable to sudden changes, all adjustments and flow-meters can be eliminated, and the stability of the system is such that the "direct" types of photometry can be used with confidence to give all the accuracy necessary in routine clinical work. The optical and electrical system can thereby be much simplified, so that the overall simplification of the apparatus is very great indeed.

If flame photometry is ever to graduate from the research laboratory to its proper place in routine clinical work, more attention must be directed to simplification and less to elaborate devices designed to avoid relatively unimportant errors.

B. M. WRIGHT

MASS RADIOGRAPHY

SIR,—Your leading article of Dec 9 states "It takes time to learn to handle a new tool, even when we are guided by experts. When the tool itself is new there are no experts." And it concludes with "These considerations all suggest that we are trying to use mass radiography in the wrong way." May I point out that 'the tool' (the X-ray unit) had many experts before and at the time of the introduction of this less efficient mass producing unit, in proof of which it may be pointed out that, before the introduction of this very expensive mass radiography scheme, a criticism was published¹ containing all the points made by your leading article, and precisely the same conclusion, but stated in the more forcible words of Wilfred Trotter. That criticism was refused by various medical journals, and all the symposia presented since that time (except one in the *Postgraduate Medical Journal* of May, 1944) have excluded any critical contribution.

The figures quoted by Dr Peter Kerley in support of mass radiography, to the effect that tuberculous patients picked up by this means stayed on an average 6-7 months in hospital and there were but three deaths amongst them, whereas in a comparable control group—presumably cases with signs and symptoms notified by general practitioners—the average stay in hospital was 18 months and there were many more deaths, are open to criticism. In Birmingham (where the mass radiography unit is under the direction of Dr Halliday Sutherland) we have picked up patients with the radiographic signs of early pulmonary tuberculosis and seen these signs completely disappear within 3-6 months, and we have seen very many cases, as indeed Dr Kerley must have done, with radiographic evidence of extensive disease which has healed without the patient having been aware of its presence. These patients have not been given the expulsive stigma of tuberculosis, nor have they needlessly occupied sanatoria beds.

Patients with signs and symptoms notified by the general practitioner, and found to have extensive disease which proves fatal in spite of all chest hospital activities, are patients whom we know from experience would a few months before probably have proved negative to any radiography. That some chronic cases are missed we are well aware, they form the small proportion of patients with recurrent signs of bronchitis who do show definite radiographic evidence of tuberculosis, but this is one of the groups for which I have advised the economical use of mass radiography.

The suggestion by Dr Owen Clarke (Dec 9) that 4 x 5 in. film should be used instead of 35 mm. film

for mass radiography or the full sized film for general clinical medicine (which is assuming mass numbers) is neither economical nor sound. It is still a photograph of the screen image, and its doubtful superiority over the 35 mm film does not economically warrant its manufacture or use. For general clinical medicine its substitution for the direct radiograph as an economical measure would not yield the additional benefits which could be gained from more careful clinical selection of cases for radiography.

Mass radiography has a use in selected groups, as I have shown, but unfortunately it has fostered the erroneous teaching that progressive disease is symptomless, and the bad habit of radiography prior to adequate clinical examination—the cart before the horse—which so blinds the observer that the course, which might otherwise have been clear, is now rendered hazardous and even dangerous to the patient.

Edgbaston Birmingham

JAMES F BRAILSFORD

* * Our leading article should have given credit to Dr Brailsford for the opinions he has persistently expressed in our columns from 1941 onwards.—ED L

SIR,—Dr Hoffstaedt's article raises many issues.

There is no doubt that mass radiography is still in an evolutionary stage, seeking the most efficient methods for the discovery of symptomless tuberculosis. It is thus understandable that some units (as Dr Hoffstaedt shows) have a small turnover, while others reach a figure of 50,000 or more examinations per year.

One could question the advisability of using a mobile unit for cases referred by general practitioners, for contacts, or for antenatal cases. These groups are probably better served by static units.

Dr Hoffstaedt's, perhaps unintentional, assessment of the merits of this relatively new method in terms of "investment and dividends" cannot be allowed to pass without comment. Once doctors start on financial calculations in relation to man and his welfare, there is no end to the possibilities. Millions of people derive a distinct sense of well being from the knowledge that they are, for the moment at least, free from a disease they dread, they are grateful to mass radiography. I doubt whether this knowledge can be too expensive for an increasingly tuberculosis conscious population. Let us ask the public, who pay for it.

G Z BRETT

Physician in-charge
Mass Radiography Units North West
Metropolitan Regional Hospital Board

London W9

SIR,—In his article of Dec 9, Dr Hoffstaedt produces some very interesting figures relating to the cost of mass radiography surveys. It appears to us, however, that his article is open to a certain amount of criticism.

In the first place, we feel that region no. 1 cannot be using its mass radiography units on the most economical basis. Dr Hoffstaedt says that over a period of 2½ months 2315 volunteers were examined by one unit from an area with an adult population of 53,790. That it should take a unit 10 weeks to radiograph 2000 odd individuals requires some explanation. During an 8 week period our own unit, doing a similar type of survey covering approximately the same adult population, radiographed 10,200 volunteers, and this survey included large films and clinical examinations. During this time the mobile unit moved seven times to various factories, school clinics, and so on. The target for one mobile unit should be at least 35,000–40,000 examinations per annum, and in many cases this figure can be considerably exceeded.

In "suggested uses for mass radiography" Dr Hoffstaedt has included dusty occupations such as mining, sand blasting and steel dressing. The use of a miniature set for this type of work is perhaps open to objection. The Pneumoconiosis Research Unit, for instance, uses microphotography for the non-mining population of the Rhondda Fach Valley whereas the mining population is being radiographed on full sized films.

Dr Hoffstaedt also proposes that school leavers should be one of the main groups for examination. This group is recognised as having the lowest incidence of tuberculosis discovered in any surveys, and we suggest that it is far more important to examine these individuals after they have been in industry for a year or two.

As used at present, mass radiography is essentially a chest service in which all abnormalities discovered are dealt with, thus includes both pulmonary and cardiac abnormalities.

If it were wished to really cheapen this service, the following action would be necessary.

The service would have to be regarded purely as a new for pulmonary tuberculosis, taking miniature films and repeat films of 4 × 5 in size. The staff could then be reduced to radiographer, assistant radiographer, dark room technician, and two clerks, clerical work would be cut down to an irreducible minimum and all cases immediately referred to a chest clinic. The post of medical director would be abandoned, and a consultant chest physician would attend for two or three half sessions per week to read the miniature and large films. All surveys would be arranged by a secretary under the direction of the consultant chest physician.

These measures would greatly lessen the cost of running mass radiography in this country. Whether this is advisable at present is, however, questionable.

PAY IN THE FORCES

SIR,—In your annotation of Dec 9, you draw attention to the discrepancy between specialist pay in the National Health Service and in the Armed Forces. An even more anomalous position will arise in the event of mobilisation, when a consultant employed on a full basis and doing domiciliary visits may be earning £310 exclusive of private work, and in addition may be receiving a merit award of another £500 or £1500. On mobilisation his salary for service away from his family and paid from the same ultimate source will drop, even as a lieutenant colonel with specialist pay, to about £1330. In the present state of international unrest, should not this situation be faced as a matter of urgency?

G D KERSLEY
Colonel A.M.S. (T.A.)

Bath

MYXEDEMA FROM RESORCINOL OINTMENT

SIR,—The failure of Dr Klein and his colleagues to produce goitres in rabbits treated with resorcinol, reported in their letter of Dec 9, may have been due to the method of administration.

After subcutaneous injection the drug is very rapidly absorbed, metabolised, and excreted. Thus, assuming that one injection per day was given, their rabbits' thyroids may well have been free of influence from the drug for 20 out of the daily 24 hours. This is in striking contrast to methylthiouracil, much of which is retained both concentrated in the thyroid and bound to the plasma proteins. The cases of myxedema reported by Bull and Fraser¹ presumably had a blood level of resorcinol maintained by continued absorption from the ointment applied to the varicose ulcers. The anti-thyroid activity was demonstrated by Domach and Fraser² in rats killed up to 2½ hours after subcutaneous injection of the resorcinol. This short period was chosen purposely because of the expected rapid metabolism and excretion of the drug.

The production of goitres by resorcinol in animals will almost certainly require a long course of frequent subcutaneous injections or skin injections, repeated many times during the day as is required to maintain

1 Bull G M, Fraser R. *Lancet* 1950 i 851.
2 Domach I, Fraser R. *Ibid* p 853.

anti-thyroid level of the drug in the blood. An experiment of this type has recently been started at the Postgraduate School. A small number of rats are receiving twice daily skin injections of resorcinol in an attempt to see if they develop goitres.

It is, however, relevant that all our patients had a cure and myxœdema, both of which subsided on withdrawal of the resorcinol.

Obituary

GEORGE HUGH CULVERWELL

O.B.E., B.A. M.D. DUBL. D.P.H.

Dr Culverwell, chief inspector to the Home Office under the Cruelty to Animals Act, died on Dec 9. He was a graduate of Trinity College, Dublin, where he obtained Stewart scholarship the Purser medal and the medal of the Dublin University Biological Association before he took his M.B. in 1913. During the 1914-18 war he held a commission as major in the R.A.M.C., and on demobilisation he was for a time an assistant medical inspector of schools for Berkshire. This work led to his appointment to the children's branch of the Home Office. In 1925 he published a paper on Feeding in Home Office Schools based on his work as inspector of reformatories and industrial schools.

G. S. M. writes: 'The Cruelty to Animals Act, for which Culverwell was chief inspector under the Home Office, became law more than 70 years ago and since there has never been a prosecution completed under the Act no case-law on experiments on living animals exists. The proper administration of the Act therefore calls for high qualities of understanding and clarity of thought of medical and scientific knowledge and experience and of ability to discriminate between the letter and the spirit. In all of these Culverwell excelled. He had a prodigious memory, and the mental quality that so often accompanies that attribute forced him to spend himself to the uttermost. His death is a challenge to the common belief that no man ever died of too much work for he was never, at least in recent years, a man of robust health and there can be no doubt that had he taken his duties more lightly he might well have survived to enjoy the retirement for which his many accolades promised so well.'

Notes and News

TUBERCULOSIS RESEARCH

In its latest annual report the research committee of the British Tuberculosis Association outlines investigations which are continuing or are being initiated, often in conjunction with other bodies. These include a study of the most favourable type of case for treatment with thiosemicarbazone, an investigation into the incidence and nature of tuberculous tracheobronchitis in this country, a survey of histoplasmosis, a controlled trial to determine the value of streptomycin in tuberculous endometritis, and a small investigation to determine the persistence of allergy after BCG vaccination. The committee has so far sought mainly to provide a sorting house for ideas, but it hopes that interested organisations or individuals will contribute money for research grants. The hon. secretaries are Dr J. V. Hurford, King George V Sanatorium Godalming and Dr Maher Loughnan, Colindale Hospital London N.W.9 and the hon. treasurer is Dr G. S. Todd, King Edward VII Sanatorium Midhurst.

ABBREVIATIONS

With his index of abbreviations used in English, French, German, Spanish, Italian, Danish and Swedish medical publications, Alfred Pevsner tries to release the reader bogged down in a morass of initials. Between the multilingual prefaces and the index proper is a separate explanation of abbreviations used in the text. From this it is surprising to learn that 'stet' means nomenclatura stethoscopica internationalis 1913. A work of this sort is bound to be uneven, but it is strange to find that though A.I.D. is defined (as 'Artificial Insemination Donator') A.I.H. is omitted. The range of the index may be illustrated by A.L.W. (arch loop whorl of Galton's finger print system) and S.H.M.O.

A CRITIC OF EDUCATION

It has been well said that the hardest thing a man is called upon to do is to think. Sir Sheldon Dudley feels that our present educational system does not give the potential thinker much help. He regards it as a very complicated and expensive system giving barren results. And why is this so? Largely because the rewards of the teaching profession are so low, the right men and women are available but not at the price paid to a manual labourer. In the course of his book Sir Sheldon deals with the vagaries of the herd instinct in human affairs with suggestion and auto suggestion, and with the changes in the values of words as symbols. He at least is playing his part in provoking thought.

A PORTABLE AUDIOMETER

Even slightly impaired hearing is a serious handicap, and may cause a child of normal capacity to seem backward at school. In industry, too, the worker with unpaired hearing may be at a disadvantage and can often work better if his disability is recognised and corrected with a hearing-aid. Testing for such partial deafness with a pure-tone audiometer is now the accepted method, and Messrs. Amplivox have lately produced a convenient portable audiometer (their model 70) which should be useful to school doctors and industrial medical officers. The instrument will work on either A.C. or D.C. mains and incorporates a voltage regulator which automatically compensates for mains voltage variation. Moreover, it is neat and convenient and weighs only 14 lb. It allows for air-conduction testing at 8 pure tones with frequencies of 125-8000 cycles per sec. and with a maximum intensity range of 100 decibels, in 5-decibel steps. Since there is a single zero reference, the same figures are read on the hearing loss scale for all frequencies, so it is possible, by setting the hearing loss dial at 15 or 20 decibels and checking the desired frequencies in quick succession to spot any child who cannot hear each at the chosen intensity above the normal hearing threshold. The calibration is said to be extremely accurate, all tolerances being within the requirements published by the Medical Research Council and the American Medical Association. The instrument is provided

- 1 Pars pro Toto. *Breviarum Medicum Internationale*. Stockholm: Almqvist & Wiksell, 1950. Pp. 186.
- 2 The Four Pillars of Wisdom. *A Rational Approach to a Health Education*. By Sir Sheldon Dudley, F.R.C. F.R.S. Medical director general Royal Navy 1941-46. London: C. A. Watts, 1950. Pp. 243. 6s. 6d.

Amplivox Ltd. 2 Bentlueck-street, London W 1

with one genuine and one dummy earphone, mounted on a headband; these, with the mains lead, pack into a lock up compartment in the audiometer when not in use. A drawback to the instrument is that it has not the full range of frequencies and cannot be used to test for bone conduction. Messrs Amplivox were among the first firms to produce an audiometer in this country, and their larger model is one of the best instruments of the kind now made in the world at a competitive price. However, this smaller model (which costs 80 guineas) will clearly serve a useful purpose, and is welcome.

Their latest hearing aid (model KA, Amplivox) like most other modern aids of the same type has automatic volume compression, which is specially useful to patients with perceptive deafness and low noise tolerance.

Temporary Residents

The Minister of Health has decided, after consultation with the General Medical Services Committee, that fees shall be paid to general practitioners in respect of temporary residents only where treatment has actually been given.

Future of the Tuberculosis Service

The public health section of the Royal College of Nursing is holding a conference on this subject on Saturday, Jan 13, at 2.15 P.M. at the college, Henrietta Place, London W 1. Dr Philip Ellman will be in the chair, and Dr G E Goddard will speak. Those who wish to attend should write to the secretary of the section before Jan 6.

Army Medical Exercise

Last week representatives of the army medical service of the British Commonwealth and the Western Union countries together with those of the U.S.A., Norway, Denmark, and Italy, attended a medical exercise at the Army School of Health, Mytchett, near Aldershot. The purpose was to discuss problems arising from exercise 'Horatius' held last May at Camberley.

Heberden Society

At the annual general meeting of this society on Dec 8 and 9, Sir Henry Cohen was elected president for 1951, with Lord Horder as president-elect. Papers were read by Prof E C Dodds, F.R.S., and Dr Peter Bishop on Endocrine Aspects of the Rheumatic Diseases, Dr Françon (Aix les Bains and Paris) on Psoriatic Arthritis, Dr James Reix on Salicylates in Rheumatic Fever, Dr Francis Bach on Splenectomy in Rheumatoid Arthritis, Dr R M Mason on Familial Ankylosing Spondylitis, and Dr C J M Clark on Psychological Factors in the Treatment of Rheumatoid Arthritis. Prof E C Kendall will give the Heberden oration in 1951.

DEPUTY ASSISTANT LONDON CHEST HOSPITAL AND MIDDLESEX
HOSPITAL

The introduction of the Blalock Taussig (1945) operation in the treatment of pulmonary stenosis marked the beginning of a new era in the handling of many cases of congenital cyanotic heart disease. The original operation has been followed by modifications, such as those introduced by Potts et al (1946), and there have been alternative methods of approach by a direct attack on the pulmonary narrowing or on the valve, as initiated by Brock (1948, 1949) and Sellors (1948).

Results of the operation have been published in several articles, and the series now presented may illustrate some of the developments in this form of surgery. Under the general heading of congenital cyanotic disease, Fallot's tetralogy provides by far the greatest number of examples, tricuspid atresia, transposition of the great vessels, and pure pulmonary stenosis are also encountered but much less frequently.

MATERIAL

This series consists of 72 cases in which operation was undertaken for the relief of the congenital cyanosis. These patients have all been followed up for at least six months. 30 were males, and 42 were females, 49 were in the age group 5-15 years.

At the start it was felt that the ideal age for surgery was between 5 and 15 years, and thus we still feel is the most satisfactory age group, but younger children have been operated on without undue difficulty. In patients over 20 the operation did not go so smoothly, but successful anastomoses were made in 6 patients over this age, the oldest being 35.

The conditions for which operation was undertaken were

Typical Fallot's tetralogy	65
Situs inversus and Fallot's tetralogy	2
Transposition of great vessels	2
Tricuspid atresia	1
Pulmonary stenosis only	2
	72

Associated abnormalities were

Gross venous anomalies (e.g., bilateral venæ cavæ)	8
Right-sided aortic arch	18
Chest wall deformity (absence of lowest segment of sternum)	19
Absent right pulmonary artery	1

At operation wherever possible, a note was made of site of stenosis as judged by direct palpation after the pericardium had been opened. 20 patients were thought to have a valvular stenosis, and 45 an infundibular one. In 42 cases there was an obvious post stenotic bulge in the common pulmonary trunk associated with unusually large right and left pulmonary vessels. We had the impression that the shape of this post stenotic bulge was ovoid in the case of infundibular stenosis, but spherical beyond a valvular obstruction.

SIGNS AND SYMPTOMS

Cyanosis—Two dominating features have been cyanosis and dyspnoea on exertion. Of the 72 patients, 56 were

cyanosed at, or very shortly after, birth, and all had cyanosis and respiratory distress in the first year of life. The cyanosis was appreciable in all cases and extreme in some. It was closely related to the degree of polycythæmia, but not to the extent of the disability, for it was noticeable, particularly in older patients, that the greater the cyanosis the greater was the exercise tolerance, per contra, two adult patients in whom disability was extreme were only slightly cyanosed.

Dyspnoea and distress on exertion varied considerably in degree, extending from patients who were restricted to walking only 2-3 yards and had to be carried everywhere, to those who could walk slowly upstairs and even lead a normal though limited existence. In older patients the disability had often varied during their life, it had tended to lessen, and if they attained the age of 20 they could usually undertake some sedentary occupation.

Any classification of exercise tolerance is impracticable, because factors such as the speed of walking, the climate, and general health vary from patient to patient and from day to day. However, within broad limits our cases could be grouped by the distance they could walk without rest, as follows:

Less than 50 yards	21 cases
Less than 200 yards	29 "
Less than a mile	11 "
More than a mile	11 "

Squatting—Associated with dyspnoea on exertion was the tendency to adopt a characteristic squatting position which was present in 50 of our patients. Several of the adults had given up their earlier habit of squatting in favour of resting forward with their hands on their bent knees when they were out of breath.

Central Nervous System—The general intelligence, we believe, was well up to average standards, two children having attained scholarships and the majority being bright and alert mentally. However, 4 were definitely subnormal, though their deficiency might have been partly due to lack of education. It must be admitted that the mentality of most of the children is abnormal owing to their unusual upbringing, as well as to their disability. These cyanotic children are particularly precious to their parents, and, like other writers, we noted that on all occasions where possible, before and after operation, both parents attended with the child at the outpatient clinic. Chronic cerebral anoxia probably contributed to their irritability and jumpiness, for, in spite of gross cardiorespiratory insufficiency, some children were unable to keep still during their waking hours. Another common feature was shyness, and an almost pathognomonic coyness, which usually disappeared soon after operation.

Clubbing of fingers of the characteristic "drumstick" pattern was present in all except 3, who showed arachnodactyly. After successful surgery the clubbing started to diminish and in most cases the nail bed became loose and almost seemed to float on the terminal phalanx. The maximum regression of clubbing took from nine months to a year to occur.

Deformity of the chest was another frequent coincident feature in the series, and in 19 patients—i.e., over a quarter of the total—the lowest piece of the sternum was absent. This led to funnel chest in some cases, and to pigeon breast in others. Bifid ribs and abnormalities in the spinal processes were also encountered.

INVESTIGATIONS

The degree of polycythæmia was variable but the hæmoglobin, red-cell count, and packed cell volume were closely related, and any one of them could usually be predicted if either of the two others was known. In more than half the cases the hæmoglobin was between

130 and 170% (highest 200%) The highest red cell count was 10,000,000 per c mm. A platelet count was done in most cases, and it was found that this did not rise proportionately with the red cell count, and was with one exception within normal limits. This is significant, since a high platelet count has been suggested as a possible cause of thrombosis in these patients. In this series there was evidence of postoperative thrombosis on only two occasions. The average oxygen saturation of the arterial blood was 66-71%.

Detailed radiological investigations and electrocardiography, were undertaken in all patients, but with no findings different from those described by other workers. The diagnosis was made on clinical grounds in most of the cases, and we now feel that cardio angiography and catheterisation of the heart should be reserved for patients in whom there is doubt or difficulty in establishing a diagnosis. This is not to deny that these procedures are highly valuable, but we have found that most cases can be diagnosed by simpler clinical and radiological methods.

TYPE OF OPERATION

The first 3 patients were operated on through a right anterior approach, the right subclavian artery and the right pulmonary artery being anastomosed on the lines of Blalock's original description. Next we adopted a left posterolateral incision and implanted the left subclavian artery into the side of the left pulmonary artery. This was done, whichever side the arch of the aorta was situated, on 62 occasions, but a similar right-sided approach was used in the 2 cases of situs inversus. The operations for the 6 remaining patients included 2 pulmonary valvulotomies, 3 Pott's operations, and 1 right sided end to end pulmonary subclavian anastomosis. In this last case the original left sided operation had failed for technical reasons. This accounts for the total of 73 operations in 72 patients. The original pulmonary valvulotomy has already been described (Sellors 1948), but the second, which ended fatally, was an attempted division of the valve through an incision in the dilated common pulmonary artery.

Our policy has been to attempt an anastomotic operation in Fallot's tetralogy, but to define, if possible, the site of stenosis in case a more direct attack on the narrowed area or valve seemed necessary at a later date. "Pure" pulmonary stenosis is undoubtedly best treated by valvulotomy.

TECHNIQUE

The brief outlines of the usual anastomotic operation are as follows.

The anaesthetic consists of small doses of thiopentone and curare with intratracheal gas and oxygen (ether and cyclopropane are not used) and to these agents are added a paravertebral block and incision infiltration with 1/2% procaine (without adrenaline). With the patient in the lateral position, the fourth rib is resected from the transverse process forwards to the anterior axillary line. The lung is retracted and the pericardium injected with 2-4 ml of 2% procaine to reduce cardiac irritability. The left pulmonary artery is sought and dissected free, after any overlying small and tortuous vessels have been secured. The pericardium is next incised posterior to the phrenic nerve to allow the heart to be inspected and to free a greater length of pulmonary artery.

The subclavian artery is next carefully isolated from its origin up to the apex of the pleural cavity, where it gives off internal mammary, vertebral, superior intercostal, and thyroid axis branches. These or their variants are divided so that a good length of artery is available to be turned down over the aortic arch and approximated to the pulmonary artery. Unexpected and abnormal branches are commonly encountered and must not be ignored. A clamp is placed across the origin of the subclavian artery, and two control clamps of the Blalock pattern are used to occlude the proximal and distal ends of the pulmonary artery. The adventitia is thoroughly removed from both vessels and an end to side junction made with an everting type of suture.

The lumen of the subclavian artery controls the size of the anastomosis, assuming that there is little or no narrowing at the suture line, but we have found that an apparently small opening, say of 2 or 3 mm diameter in a small child has given a much better functional result than might have been expected. The slight angulation of the subclavian artery over the aortic arch does not seem to interfere with the efficiency of the anastomosis, but with a right-sided arch and a left innominate artery the subclavian artery lies in a mechanically better position.

COMPLICATIONS

There is no doubt that increasing experience and cooperation between the various members of the team contribute to improved results. In our first 25 cases there were 6 deaths at or within a short time of operation but in the subsequent 68 cases (not all included in this series) there has been only 3 fatalities. Similar observations have been made by other surgeons.

The causes of the 9 operation deaths varied. 2 patients died of cardiac irregularity in the early stages of the operation, 4 more died of probable heart failure within twenty-four hours (no more obvious cause could be found at necropsy). There was 1 death from thrombosis at the anastomotic line, and 1 from a clotted haemothorax which produced gross mediastinal displacement. In addition, there was 1 death three weeks after operation, thought to be due to cerebral thrombosis on the day that the child was due to return home.

Complications on the whole were uncommon, but some of these were alarming. Two patients both over 24 hours had large haemorrhages of more than 6 pints shortly after operation. These were almost certainly due to a tear in the suture line as the large pulmonary artery became distended. A transfusion of blood and plasma was given immediately, but in one case the initial fall in blood pressure led to ischaemia in the left arm, whose main artery had been ligated. The subsequent Volkmann's contracture made a corrective operation necessary. The other serious complication occurred in the oldest patient, aged 35, whose lung was affected by tuberculosis, after operation a tension pneumothorax persisted for some days in spite of continuous aspiration and the temporary loss of lung function was followed by a slight hemiplegia presumably due to anoxia. There was 1 case of pleural infection. A transitory Horner's syndrome was observed in 16 patients. The skin wound generally healed badly in comparison with those of other thoracotomies.

RESULTS

Apart from these complications, the average postoperative convalescence was straightforward, and most of the children were discharged within 12-14 days with obvious clinical signs of improvement. The increase in exercise tolerance was the most marked feature and dated from the time of operation, progressively improving up to a period of 3 or 4 months, and in some cases was further benefit up to 6 or 9 months.

The cyanosis improved gradually after operation in most cases but often took from three to six months to reach its final level. Again the degree of improvement of the cyanosis bore little relation to the extent of the decrease of the disability. The reduction in polycythemia was unpredictable, sometimes showing an early pronounced fall, and on other occasions altering only a small extent over the first few months. The heart increased in size slightly as the left ventricle enlarged but only in 3 cases has there been any considerable cardiac enlargement.

In several patients a fever developed postoperatively which was unassociated with leucocytosis and often persisted for two or three weeks. These children were unaffected by chemotherapy, and we could not find a cause in any of them for their persistent temperature.

patients returned (1 at three weeks and 1 at seven postoperatively) with signs of cardiac failure with fever and tachycardia. In neither could an ablish a diagnosis of infective endocarditis despite blood culture but in both of them the fever died to penicillin and the signs of cardiac failure cleared. One of these patients had a large pericardial effusion. This complication has also occurred in other cases but the effusion eventually cleared itself in both.

patient (a woman of 22, weighing 16 stone), who was cyanosed before operation and had a marked excessive increase in exercise tolerance, died suddenly over a year later. Post mortem no cause of her death could be discovered. The heart showed a typical tetralogy with a patent adequate anastomosis but, however, had two previous attacks of unconsciousness from which she had recovered herself.

an accurate classification of the end results is impracticable, because there are too many variable factors to be considered. All the patients and the parents were psychologically from the operation, and improvement has to be judged from the base line of the original life. We have regarded a good result as one in which a child has been able to take up ordinary school work without violent exercise, or in which an adult can live on his or her own living in a normal manner. Two patients are particularly worthy of mention—one who had football and was getting into trouble for fighting, another who failed to attend outpatients as it was away from his school sports where he ran (allegedly) sprints in 12 seconds. Several adults who worked in a workshop eight hours a day and found time to dance and amuse themselves have also been encountered. In this category have been placed 42 patients. An additional 22 were added as being considerably benefited in that they had much increased exercise tolerance but were still limited by excessive exertion.

the remaining 7 patients, 2 could not be expected to be benefited because the anastomosis was made erroneously on the wrong side of transposition of the great vessels. The other 5 did not improve appreciably for reasons which were not probably owing to inadequacy of the anastomosis. However, the parents of one of the 2 patients in this category expressed interest in the physical improvement of their child, and in this may well be wishful thinking.

at the future holds for these patients cannot be predicted, but the early results have proved most encouraging. If the artificial "ductus" does not give the desired effect or maintain the improvement, an anastomosis on the opposite side, or a direct attack on the stenosed area, may still be considered.

SUMMARY

series of 93 patients have been operated on for congenital cyanotic heart disease. There were 9 deaths immediately upon the operation, but the mortality was proportionately higher in the early cases than in the recent ones. The majority of cases were examples of tetralogy of Fallot's tetralogy. These patients, 72 have been followed up for six years or more. The clinical features and investigations have been briefly described.

The technique adopted in most cases was the performance of a left end-to-side Blalock type of anastomosis on the pulmonary and subclavian arteries using the terolateral approach. The pericardium was opened and the heart and site of the stenosis exposed.

The end result as judged through periods ranging from six months to two and a half years were gratifying. Twenty patients died suddenly a year after operation, and

7 were regarded as not improved, but very marked benefit was obtained by 42 patients who were previously severely disabled, and a further 22 gained considerable benefit in exercise tolerance and general health.

BEFORE direct measurement of the pressure in the pulmonary artery and right ventricle of patients with mitral stenosis was made possible by cardiac catheterisation, the state of the pulmonary circulation was deduced from indirect evidence. Breathlessness on exertion, paroxysmal dyspnoea, haemoptyses, accentuation of the pulmonary second sound, increased prominence of the pulmonary vascular shadows, dilatation of the pulmonary artery, enlargement of the right ventricle, and electrocardiographic changes were accepted as indicating increased pressure in the lesser circulation. Renewed interest in the surgical treatment of mitral stenosis has made it advisable to determine how far these symptoms and signs are a reliable guide to the extent of pulmonary hypertension.

The pressure in the pulmonary artery and right ventricle* of patients with mitral stenosis has been measured by a number of workers. Bloomfield et al (1946) found increased right ventricular pressures in 5 patients with mitral stenosis, of whom 4, who had right sided failure or were just recovering from it, had pressures ranging from 85/16 to 103/29 mm Hg (upper limit of normal 30/4), in the 5th, who had never had right sided failure, there was a less pronounced rise of pressure (43/2 mm Hg). Few clinical details were given concerning these patients and no attempt made to correlate the physical findings with the pressure measurements. Similarly Lagerlof and Werko (1949a) give few details of their 5 patients, 2 of whom had aortic incompetence in addition to mitral stenosis. 2 patients were not in failure, the pulmonary artery pressure being normal in one and slightly elevated in the other, the other 3 had peripheral venous congestion with high pulmonary pressures. Harken et al (1948, 1950) Bland and Sweet (1949), Bailey et al. (1950), and Baker et al (1950) report the right ventricular or pulmonary artery pressures in 17 patients selected for surgical relief of mitral stenosis. Most were under 40, their symptoms were predominantly pulmonary, and only 5 had had systemic congestion. Those with pulmonary

* The systolic pressures in the right ventricle and pulmonary artery are identical.

symptoms only had markedly elevated pressures, which in 2 exceeded the systemic arterial pressure. In addition to left atrial enlargement, many had an enlarged right ventricle with prominence of the conus region and often increased vascular markings. The electrocardiogram usually showed right axis deviation or right ventricular hypertrophy, but no particular correlation was made between the radiological and electrocardiographic findings and the extent of pulmonary hypertension.

Borden et al (1950) have correlated the pulmonary-artery pressure with the functional state of 30 patients with mitral stenosis, 10 of whom had aortic incompetence without significant enlargement of the left ventricle. There was a rough direct correlation between the pressure and the patient's functional capacity. Those who were partly or completely incapacitated by exertional dyspnoea usually had a high pulmonary-artery pressure and a 25% reduction in cardiac output. On fluoroscopy patients with normal or slightly raised pressures had a normal cardiac shadow or straightening of the left border of the heart with left atrial enlargement. Severe pulmonary hypertension was associated with enlargement of the pulmonary artery and right ventricle, and a reticular or finely mottled appearance of the

lungs. Although the left atrium was enlarged, there was no exact correlation between the size of this chamber and the extent of pulmonary hypertension.

Hickam and Cargill (1948) have studied the effect of exercise on the cardiac output and mean pulmonary artery pressure in normal subjects and in patients with mitral stenosis. In the former the cardiac output increased without any conspicuous rise in pulmonary artery pressure. In the latter exercise produced a striking rise in pulmonary artery pressure with little or no increase in cardiac output. Other workers have observed a similar response (Bland and Sweet 1949, Baker et al 1950, Harken et al 1950). The pulmonary artery pressure depends on the cardiac output and the resistance offered by the left atrium and the pulmonary vascular bed. The rise in output without a proportionate increase in mean pulmonary artery pressure, which is found in normal subjects, must signify a corresponding decrease in resistance to blood flow through the lungs. Observations by Hamilton et al (1939) in dogs and by Courman (1947) in man suggest that this reduction in pulmonary resistance is due to the opening of new channels or the widening of those already open. In mitral stenosis the rise in pressure without a corresponding rise in cardiac output must be due to an increase in pulmonary vascular resistance.

Long standing mitral stenosis may cause sclerotic changes in the pulmonary vascular bed (Parker and Weiss 1936, Larrabee et al 1949), but how far these changes contribute to the rise in pulmonary artery pressure at rest and on exercise is not yet known.

METHODS AND MATERIAL

The pressure in the right ventricle or pulmonary artery was measured by the technique described previously (Bayliss et al 1950). We have used the right ventricular systolic pressure as a measure of the pulmonary artery systolic pressure, an agree with Bloomfield et al (1946) that the normal range is 18–30 mm Hg. The slight difference between the pulmonary

Fig. 1—Postero-anterior telecortgenograms of 2 patients with mitral stenosis. (A) patient no. 3 (right ventricular pressure at rest 24/1 mm Hg). (B) patient no. 22 (right ventricular pressure at rest 105/14 mm Hg). Both radiographs show marked prominence of the pulmonary artery and enlargement of the heart to right and left. In (A) enlargement of the left atrium was evident from the double contour on the right border. Although the resting ventricular pressure was normal in one patient and very high in the other, there is no significant difference in the cardiac outlines.

artery and the right ventricular systolic pressure in an individual patient is due to normal fluctuations as the catheter is moved from the ventricle to the pulmonary artery. The end diastolic ventricular pressure indicates the tension in the right ventricle just before contraction and closely parallels the right atrial pressure. The normal end diastolic pressure seldom exceeds 4 mm Hg.

The effect of exercise was studied in a number of cases. The patient, remaining supine, carried out bicycling movements with his legs against manual resistance. When a steady state was reached, the oxygen consumption was measured by a Douglas bag and Haldane gas analysis. Immediately after the exercise samples of arterial and mixed venous blood were taken simultaneously, and the right ventricular or pulmonary artery pressure and the systemic arterial pressure recorded.

Of 22 patients who were studied, 13 had involvement of the mitral valve only, 9 had, in addition to mitral stenosis, other valvular lesions which were not regarded as playing a major part in the haemodynamic state. Thus none of the patients with auscultatory evidence of aortic incompetence had peripheral signs of aortic reflux, although 5 (nos. 2, 10, 16, 18, 19) had slight or moderate left ventricular enlargement on fluoroscopy. One patient (no. 4) had associated systemic hypertension, but this did not influence the pulmonary artery pressure, which was normal. Brief clinical details of each case are given in an appendix†

RESULTS

In table I the cases are arranged in ascending order of their right ventricular systolic pressure at rest. In 5, pressures were within normal limits, in 17 there was pulmonary hypertension with systolic pressures ranging from 32 to 105 mm Hg.

Relation of Clinical State to Pulmonary Pressure.—There was some correlation between exercise tolerance and the pulmonary artery pressure, patients with normal systolic pressures usually being less incapacitated than those with raised pressures. There were, however, several exceptions. For instance, patient no. 3 had a normal

Fig. 2.—Electrocardiograms showing right ventricular hypertrophy in patients with mitral stenosis. Patients nos. 15–22 had severe pulmonary hypertension at rest. Patient no. 3 had a normal pressure at rest which rose to 85/13 mm Hg on exercise.

right ventricular pressure at rest of 24/1 mm Hg but was unable to do even light housework because of dyspnoea. In contrast, patient no. 16 had an increased pulmonary artery pressure of 54/29 mm Hg but was able to do her housework except for heavy lifting.

Of the 17 patients with pulmonary hypertension 11 had no evidence of peripheral venous congestion, although the hypertension was severe in 5, the pressure ranging from 53 to 92 mm Hg. Of the remainder, 5 had obvious venous congestion with oedema at the time of observation, and the 6th (no. 22) had engorged neck veins but no oedema; their pulmonary artery systolic pressures ranged from 36 to 105 mm Hg, and they all had an increased end diastolic right ventricular pressure in keeping with venous congestion.

The 3 patients (nos. 20–22) with the highest pulmonary pressures presented a distinctive clinical picture. They were young, their symptoms were intense dyspnoea on slight exertion, orthopnoea, haemoptyses, and episodes

* Following exercise pulmonary artery pressure was measured 4 min. after right ventricular pressure.

of so called "bronchitis" with copious frothy sputum. Although peripheral venous congestion had occurred in 2 (nos 20, 22) it was transient and not a conspicuous feature of their illness. Their condition deteriorated rapidly, and they died of pulmonary oedema within three years of the onset of symptoms. Until the onset of symptoms they often had had remarkable effort tolerance.

A further 5 patients (nos 15-19) had severe pulmonary hypertension of similar degree (53-92 mm Hg). One (no 15) was a young man with a short history of marked dyspnoea on exertion and of hæmoptyses, his clinical picture was similar to that seen in the patients with the foregoing pulmonary symptoms without conspicuous right-sided failure. 2 patients (nos 18, 19) had marked peripheral venous congestion and oedema at the time of observation. The other 2 (nos 16, 17) were free of peripheral venous congestion, and although their main symptom was dyspnoea, they did not present the features of the pulmonary syndrome.

There was no correlation between the duration of the patient's symptoms and the degree of pressure increase. Thus patient no 5 had had several episodes of congestive failure in the last ten years but still had a normal pressure at rest, whereas patient no 20 had been free of symptoms until eighteen months before admission, and had a right ventricular pressure of 92/1 mm Hg. Neither had peripheral venous congestion or oedema at the time of observation.

Fluoroscopy—Left atrial enlargement was present in all patients except one (no 1), but there was no correlation between its extent and the degree of pulmonary hypertension. The diagnosis of a significant degree of mitral incompetence was confirmed in 2 patients (nos 10, 16) by systolic expansion of the left atrium.

Enlargement of the pulmonary artery was present in all patients (fig 1). Every patient with pulmonary hypertension at rest showed right ventricular enlargement, which was most marked in those with the highest pressures. 2 patients (nos 3, 8) with normal or nearly normal pressures at rest also had conspicuous right ventricular enlargement.

Electrocardiograms—In 17 of the 19 patients in whom the electrocardiographic position could be determined, the heart was in a vertical or semi vertical position with clockwise rotation. There was no correlation between the presence of auricular fibrillation and the degree of pulmonary hypertension. 7 patients had sinus rhythm, and, except for the patient with a normal pressure (no 1), all had wide and notched P waves. There was a striking correlation between the presence of a very high pulmonary artery pressure and electrocardiographic evidence of right ventricular hypertrophy, using criteria based on the findings of Wilson et al (1941, 1947). The 4 patients with predominant pulmonary symptoms (nos 15, 20-22) all showed right ventricular hypertrophy (fig 2). One patient (no 3) with normal resting pressures also had right ventricular hypertrophy (fig 2), she had enlargement of the right ventricle on fluoroscopy, and her response to exercise is discussed below. 3 exceptions with marked pulmonary hypertension (nos 16, 18, 19) did not show electrocardiographic evidence of right ventricular hypertrophy, their mitral stenosis was complicated by aortic incompetence with enlargement of both right and left ventricles.

Response to Exercise—In contrast to normal subjects, in whom an increase in cardiac output occurs without a rise in pulmonary-artery pressure, all the patients who were exercised showed a significant increase in right-heart pressures (table II). The greatest increase occurred in patient no 3, in whom a normal resting right ventricular pressure rose to 85/13 mm Hg. These increases in pulmonary vascular pressure were not accompanied by

a significant rise in cardiac output or in systemic arterial blood-pressure. It is clear therefore that this reaction resulted from an increase in pulmonary vascular resistance.

DISCUSSION

Clinical Recognition of Pulmonary Hypertension in Mitral Stenosis—It is apparent that in patients with mitral stenosis the pulmonary vascular pressures range from normal to very high, and that cardiac failure with peripheral venous congestion is associated with elevated pulmonary artery and right ventricular pressures. On the other hand, patients without congestive failure may have raised or normal pulmonary vascular pressures, and it is with this group that we are particularly concerned.

The presence of severe pulmonary hypertension at rest can be diagnosed from the clinical findings. The patients are usually in the third or fourth decade, and present a distinct syndrome characterised by episodes of acute pulmonary oedema, which may be precipitated by exertion or excitement. Similar cases have been described by Gallavardin (1921) and by McGinn and White (1934). Milder pulmonary congestion is characterised by episodes, lasting 2-4 weeks, in which there is increased dyspnoea on exertion, orthopnoea, cough with expectoration of frothy sputum and occasionally hæmoptyses. Secondary infection, producing purulent sputum may follow, and the condition then simulates acute bronchitis. Our patients died of pulmonary oedema within 2-3 years of the onset of symptoms, and peripheral venous congestion was not a conspicuous feature of the clinical course. On fluoroscopy there was considerable enlargement of the right ventricle in addition to prominence of the pulmonary artery and left atrium. There was also electrocardiographic evidence of right ventricular hypertrophy.

Patients with normal or moderately raised pulmonary vascular pressures also had diminished exercise tolerance. All had enlargement of the left atrium and pulmonary artery, but with one exception only those with pulmonary hypertension at rest had enlargement of the right ventricle. In the exceptional case (no 3) whose exercise tolerance was much reduced, the right ventricular pressure was normal at rest, but there was right ventricular enlargement and electrocardiographic evidence of right ventricular hypertrophy. Mild exercise caused a threefold rise in the right ventricular pressure, and perhaps therefore during her normal daily activity the patient usually had pulmonary hypertension. Thus a normal pressure at rest does not eliminate the possibility of pulmonary hypertension with ordinary activity.

None of our patients with severe pulmonary hypertension had reticulation or mottling of the lungs. We have records of two patients, not included in this series who had mitral stenosis and pulmonary hæmosiderosis. Their mean pulmonary artery pressures were 25 and 29 mm Hg respectively (normal 15 mm Hg). They both gave a history of recurrent and often severe hæmoptyses over a period of nine years, but dyspnoea was minimal. They did not have any of the other clinical features of patients with severe pulmonary hypertension.

Mechanism of Pulmonary Hypertension—The primary factor responsible for the development of pulmonary hypertension in mitral stenosis is the mechanical obstruction offered by the diseased valve. Thus it is apparent from the narrowing of the valve orifice, the congestion of the pulmonary veins, and the histological changes found in the pulmonary capillaries. Direct measurement in operation on patients with severe mitral stenosis has confirmed that the left atrial pressure may reach as high as 30-40 mm Hg (Bland and Sweet 1948). By passing a catheter through the right heart so as to occlude a distal branch of the pulmonary artery, Hellem

TABLE III—PULMONARY ARTERY AND PULMONARY CAPILLARY PRESSURES IN 5 CASES OF MITRAL STENOSIS

Case no	Mean pulmonary artery pressure (mm Hg)	Mean pulmonary capillary pressure (mm Hg)	Mean pulmonary artery/pulmonary capillary gradient (mm Hg)
Normal values	15	10	5
2	21	17	4
10	25	21	4
12	30	23	7
16	42	23	19
17	51	36	15

et al (1948, 1949), and Hickam (1949a and b) have measured the pressure in the pulmonary "capillaries" of normal subjects, and shown in dogs and in man (with atrial septal defects) that this is closely parallel to the pressure in the left atrium. The normal mean pulmonary "capillary" pressure by this technique is 10 mm Hg (range 7–15 mm Hg). In mitral stenosis Lagerlof and Werko (1949b) and Dexter et al (1950) report values ranging from 18–40 mm Hg—further evidence of the increased pressure in the left atrium and pulmonary veins.

However, the anatomical factor alone cannot account for all the increase in pulmonary artery pressure, because (a) without a change in cardiac output the pressure rises on exercise, and (b) the presence or absence of failure may raise or lower the pressure, presumably without change in the size of the stenosed orifice (Bloomfield et al 1946, our own observations). In these circumstances there is an increase in pulmonary vascular resistance which is reversible.

Dexter et al (1950) have shown that with lesser degrees of pulmonary hypertension the pulmonary artery pressure is increased in proportion to the pulmonary "capillary" pressure, and that the pressure gradient from the pulmonary artery to the pulmonary "capillaries" and the pulmonary arteriolar resistance are normal. This indicates that lesser degrees of pulmonary hypertension are due to the obstruction offered by the stenosed valve. With more severe pulmonary hypertension, however, the pulmonary artery pressure is raised out of all proportion to the rise in pulmonary "capillary" pressure, indicating an increase in pulmonary arteriolar resistance. Our own limited observations

confirm these findings (table III). Thus it seems that increased pulmonary arteriolar resistance plays an important part in the development of severe hypertension in mitral stenosis. This increased resistance may be due to pulmonary arteriolar vasoconstriction or to structural changes in the vessels. Parker and Weiss (1936) have described in detail the histological changes in the lungs of patients with the clinical features of severe pulmonary hypertension. In the 2 patients (nos 20, 22) in our series who came to autopsy and had severe pulmonary hypertension, hyperplastic sclerosis and intimal thickening was present in some of the pulmonary arteries and arterioles (fig 3), providing direct evidence of the possibility of structural changes playing a part in the increase in resistance. We are unable to determine the presence, or assess the significance, of a persistent pulmonary vasoconstriction, but it is likely that, as in essential systemic hypertension, an increase in arteriolar tone precedes permanent structural changes.

SUMMARY

In 22 patients with mitral stenosis the right ventricular and/or pulmonary artery pressures have been correlated with clinical, radiological, and electrocardiographic findings. Pulmonary hypertension at rest was found in 17 patients. In general, those with the most severe symptoms had the highest pressures, but the duration of symptoms was not related to the degree of pulmonary hypertension.

Patients with severe pulmonary hypertension without peripheral venous congestion presented a recognisable syndrome characterised by predominant pulmonary symptoms and electrocardiographic evidence of right ventricular hypertrophy. Patients with lesser degrees of pulmonary hypertension did not present characteristic features, but right ventricular enlargement on fluoroscopy was a constant finding. The degree of pulmonary hypertension, however, can be determined only by direct measurement.

Right ventricular enlargement was found in all patients with pulmonary hypertension. There was no relation between the size of the left atrium and the degree of pulmonary hypertension.

On exercise a striking rise in pulmonary artery pressure occurred without a significant increase in cardiac output. The pulmonary hypertension at rest and on exercise is due to stenosis of the mitral valve and to

Fig 3—Patient no 22, with severe pulmonary hypertension. (A) Small pulmonary artery showing fibrous intimal endarteritis; the surrounding alveoli are filled with heart failure cells ($\times 205$). (B) Pulmonary arteriole showing gross intimal fibroblastic hyperplasia; the adjacent intra-alveolar capillaries are distended ($\times 580$).

of so called "bronchitis" with copious frothy sputum. Although peripheral venous congestion had occurred in 2 (nos 20, 22) it was transient and not a conspicuous feature of their illness. Their condition deteriorated rapidly, and they died of pulmonary oedema within three years of the onset of symptoms. Until the onset of symptoms they often had had remarkable effort tolerance.

A further 5 patients (nos 15-19) had severe pulmonary hypertension of similar degree (53-92 mm Hg). One (no 15) was a young man with a short history of marked dyspnoea on exertion and of hæmoptyses, his clinical picture was similar to that seen in the patients with the foregoing pulmonary symptoms without conspicuous right sided failure. 2 patients (nos 18, 19) had marked peripheral venous congestion and oedema at the time of observation. The other 2 (nos 16, 17) were free of peripheral venous congestion, and although their main symptom was dyspnoea, they did not present the features of the pulmonary syndrome.

There was no correlation between the duration of the patient's symptoms and the degree of pressure increase. Thus patient no 5 had had several episodes of congestive failure in the last ten years but still had a normal pressure at rest, whereas patient no 20 had been free of symptoms until eighteen months before admission, and had a right ventricular pressure of 92/1 mm Hg. Neither had peripheral venous congestion or oedema at the time of observation.

Fluoroscopy—Left atrial enlargement was present in all patients except one (no 1), but there was no correlation between its extent and the degree of pulmonary hypertension. The diagnosis of a significant degree of mitral incompetence was confirmed in 2 patients (nos 10, 16) by systolic expansion of the left atrium.

Enlargement of the pulmonary artery was present in all patients (fig 1). Every patient with pulmonary hypertension at rest showed right ventricular enlargement, which was most marked in those with the highest pressures. 2 patients (nos 3, 8) with normal or nearly normal pressures at rest also had conspicuous right ventricular enlargement.

Electrocardiograms—In 17 of the 19 patients in whom the electrocardiographic position could be determined, the heart was in a vertical or semi vertical position with clockwise rotation. There was no correlation between the presence of auricular fibrillation and the degree of pulmonary hypertension. 7 patients had sinus rhythm, and, except for the patient with a normal pressure (no 1), all had wide and notched P waves. There was a striking correlation between the presence of a very high pulmonary artery pressure and electrocardiographic evidence of right ventricular hypertrophy, using criteria based on the findings of Wilson et al (1941, 1947). The 4 patients with predominant pulmonary symptoms (nos 15, 20-22) all showed right ventricular hypertrophy (fig 2). One patient (no 3) with normal resting pressures also had right ventricular hypertrophy (fig 2), she had enlargement of the right ventricle on fluoroscopy, and her response to exercise is discussed below. 3 exceptions with marked pulmonary hypertension (nos 16, 18, 19) did not show electrocardiographic evidence of right ventricular hypertrophy, their mitral stenosis was complicated by aortic incompetence with enlargement of both right and left ventricles.

Response to Exercise—In contrast to normal subjects, in whom an increase in cardiac output occurs without a rise in pulmonary-artery pressure, all the patients who were exercised showed a significant increase in right heart pressures (table II). The greatest increase occurred in patient no 3, in whom a normal resting right ventricular pressure rose to 85/13 mm Hg. These increases in pulmonary vascular pressure were not accompanied by

a significant rise in cardiac output or in systemic arterial blood pressure. It is clear therefore that this reaction resulted from an increase in pulmonary vascular resistance.

DISCUSSION

Clinical Recognition of Pulmonary Hypertension in Mitral Stenosis—It is apparent that in patients with mitral stenosis the pulmonary vascular pressures range from normal to very high, and that cardiac failure with peripheral venous congestion is associated with elevated pulmonary artery and right ventricular pressures. On the other hand, patients without congestive failure may have raised or normal pulmonary vascular pressures, and it is with this group that we are particularly concerned.

The presence of severe pulmonary hypertension at rest can be diagnosed from the clinical findings. The patients are usually in the third or fourth decade, and present a distinct syndrome characterised by episodes of acute pulmonary oedema, which may be precipitated by exertion or excitement. Similar cases have been described by Gallavardin (1921) and by McGinn and White (1934). Milder pulmonary congestion is characterised by episodes, lasting 2-4 weeks, in which there is increased dyspnoea on exertion, orthopnoea, cough with expectoration of frothy sputum and occasionally hæmoptyses. Secondary infection, producing purulent sputum may follow, and the condition then simulates acute bronchitis. Our patients died of pulmonary oedema within 2-3 years of the onset of symptoms, and peripheral venous congestion was not a conspicuous feature of the clinical course. On fluoroscopy there was considerable enlargement of the right ventricle in addition to prominence of the pulmonary artery and left atrium. There was also electrocardiographic evidence of right ventricular hypertrophy.

Patients with normal or moderately raised pulmonary vascular pressures also had diminished exercise tolerance. All had enlargement of the left atrium and pulmonary artery, but with one exception only those with pulmonary hypertension at rest had enlargement of the right ventricle. In the exceptional case (no 3) whose exercise tolerance was much reduced, the right ventricular pressure was normal at rest, but there was right ventricular enlargement and electrocardiographic evidence of right ventricular hypertrophy. Mild exercise caused a threefold rise in the right ventricular pressure, and perhaps therefore during her normal daily activity this patient usually had pulmonary hypertension. Thus a normal pressure at rest does not eliminate the possibility of pulmonary hypertension with ordinary activity.

None of our patients with severe pulmonary hypertension had reticulation or mottling of the lungs. We have records of two patients, not included in this series who had mitral stenosis and pulmonary hæmorrhages. Their mean pulmonary artery pressures were 25 and 29 mm Hg respectively (normal 15 mm Hg). They both gave a history of recurrent and often severe hæmoptyses over a period of nine years, but dyspnoea was minimal. They did not have any of the other clinical features of patients with severe pulmonary hypertension.

Mechanism of Pulmonary Hypertension—The primary factor responsible for the development of pulmonary hypertension in mitral stenosis is the mechanical obstruction offered by the diseased valve. This is apparent from the narrowing of the valve orifice, the congestion of the pulmonary veins, and the histological changes found in the pulmonary capillaries. Direct measurement in operation on patients with severe mitral stenosis has confirmed that the left atrial pressure may reach as high as 30-40 mm Hg (Bland and Sweet 1949). By passing a catheter through the right heart so as to occlude a distal branch of the pulmonary artery, Hellem

Fig. 1—17-K.S. excretion in cases in which suprarenal overaction was suspected: white squares female, black squares male.

and the 17-K.S. output. Of the 13 cases of Cushing's syndrome 7 showed a moderately increased 17-K.S. excretion the maximum being 43 mg in twenty-four hours in a woman with basophilism and virilism. Normal 17-K.S. excretion was found, however, in 2 fatal cases of florid basophilism. Fig. 1 shows that obese patients with the clinical features of Cushing's syndrome show a group tendency to increased 17-K.S. output compared with patients with simple obesity, but the estimation has a very limited value in the individual case. A more consistent difference is found between cases of virilism and simple hirsuties, but here again there are individual exceptions.

In only 1 patient in the whole series was 17-K.S. excretion sufficiently high to support the diagnosis of secreting adrenal tumour. The excretion value rose to 98 mg in twenty-four hours. On exploration adrenal hyperplasia alone was found. The adrenals were examined at operation or at necropsy in 9 other cases without any tumours being found, but adrenal hyperplasia was reported in 3 cases. In none of the remainder of the series did the subsequent clinical course provide any final proof of adrenal tumour.

2. Decrease in 17-K.S. Excretion Expected (fig. 2)

Addison's Disease.—In the 7 verified cases of Addison's disease there was a great decrease in 17-K.S. excretion, which was usually less than 1 mg in twenty-four hours in women and less than 3 mg in twenty-four hours in men. The diagnosis of Addison's disease was not substantiated in 6 patients tested, and 4 of these had normal levels of 17-K.S. excretion, the 2 others had severe chronic illness, and in both of them the 17-K.S. excretion was reduced to 2 mg in twenty-four hours. In 1 case of Addison's disease determinations were made throughout pregnancy, the 17-K.S. excretion gradually rose from nil before pregnancy to a maximum of 14 mg in twenty-four hours in the last month of pregnancy. After labour 17-K.S. excretion decreased rapidly in three days to nil.

Primary Pituitary Failure.—In 9 cases of Simmonds's disease (males), the 17-K.S. output was less than 2.5 mg in twenty-four hours. In 20 cases where a diagnosis of pituitary failure was considered but finally excluded (including 8 cases of anorexia nervosa) only 1 had an output as low as this. In many cases, however, especially in severe anorexia nervosa and myxoedema, subnormal levels were found. In mild anorexia nervosa 17-K.S. excretion was normal but decreased with protracted malnutrition. Repeated estimations in 1 case complicated by pulmonary tuberculosis showed an eventual decrease to 1.2 mg in twenty-four hours.

Simmonds's disease developed in 3 patients after severe post partum hemorrhage, in 1 case the 17-K.S. output was nil for the first four days of the puerperium and then increased gradually to 2 mg in twenty-four hours and remained at this level until the clinical signs of hypopituitarism became obvious. In a small series of patients estimations performed in the immediate period after normal delivery showed a decrease in excretion compared with pre partum levels but remained within the normal range.

Primary Testicular Failure.—In 7 eunuchoidal men with testicular atrophy 17-K.S. excretion was 5.5–11 mg in twenty-four hours. Estimations were also done in 14 young adults with poor development of secondary sex characters (8 had gynecomastia). Presumably no interstitial cells had been destroyed, because sexual maturity was attained later. In this group 17-K.S. output was 7–23 mg in twenty-four hours. The only inference to be drawn from this small series is that cases of testicular atrophy show a group tendency to a low normal 17-K.S. excretion which is absent in cases of delayed puberty. In the individual case a low figure has no diagnostic value, but a high normal value (over 15 mg) may be taken to indicate undisturbed testicular function.

3. Miscellaneous Conditions

Dwarfism.—In 13 cases of varying types of dwarfism associated with sexual infantilism 17-K.S. excretion was 0–11 mg in twenty-four hours. In 3 of these cases dwarfism was due to destruction of the pituitary gland by a craniopharyngioma, and the values were 0, 0.7 and 2.3 mg in twenty-four hours. In the 10 other patients the estimation was of no apparent diagnostic value.

Pituitary Tumours.—A normal result was obtained in 7 cases of acromegaly. The test was therefore of no value in confirming the diagnosis or in assessing the activity of the disease. In 7 cases of chromophobe adenoma of the pituitary gland the 17-K.S. excretion was 7.0–27.3 mg in twenty-four hours, but these values could not be correlated with the clinical evidence of endocrine function, the highest value was found in a woman with no endocrine abnormalities. In this group 3 women presented with amenorrhoea and obesity, and in them the 17-K.S. excretion was 7.0–22.5 mg in twenty-four hours.

Other Conditions.—Estimations were made in 9 cases of menstrual disturbances, 2 cases of pregnancy, 3 cases of thyrotoxicosis, 3 cases of aspermiu or impotence, and

Fig. 2—17-K.S. excretion in cases in which suprarenal underaction was suspected: white squares female, black squares male.

Fig. 1—17-K.S. excretion in cases in which suprarenal overaction was suspected: white squares, female; black squares, male.

and the 17-k.s. output. Of the 13 cases of Cushing's syndrome 7 showed a moderately increased 17-k.s. excretion, the maximum being 43 mg in twenty-four hours in a woman with basophilism and virilism. Normal 17-k.s. excretion was found, however, in 2 fatal cases of florid basophilism. Fig. 1 shows that obese patients with the clinical features of Cushing's syndrome show a group tendency to increased 17-k.s. output compared with patients with simple obesity, but the estimation has a very limited value in the individual case. A more consistent difference is found between cases of virilism and simple hirsuties, but here again there are individual exceptions.

In only 1 patient in the whole series was 17-k.s. excretion sufficiently high to support the diagnosis of secreting adrenal tumour. The excretion value rose to 98 mg in twenty-four hours. On exploration adrenal hyperplasia alone was found. The adrenals were examined at operation or at necropsy in 9 other cases without any tumours being found, but adrenal hyperplasia was reported in 3 cases. In none of the remainder of the series did the subsequent clinical course provide any final proof of adrenal tumour.

2. Decrease in 17 K S Excretion Expected (fig. 2)

Addison's Disease.—In the 7 verified cases of Addison's disease there was a great decrease in 17-k.s. excretion, which was usually less than 1 mg in twenty-four hours in women and less than 3 mg in twenty-four hours in men. The diagnosis of Addison's disease was not substantiated in 6 patients tested, and 4 of these had normal levels of 17-k.s. excretion, the 2 others had severe chronic illness, and in both of them the 17-k.s. excretion was reduced to 2 mg in twenty-four hours. In 1 case of Addison's disease determinations were made throughout pregnancy, the 17-k.s. excretion gradually rose from nil before pregnancy to a maximum of 14 mg in twenty-four hours in the last month of pregnancy. After labour 17-k.s. excretion decreased rapidly in three days to nil.

Primary Pituitary Failure.—In 9 cases of Simmonds's disease (males), the 17-k.s. output was less than 2.5 mg in twenty-four hours. In 20 cases where a diagnosis of pituitary failure was considered but finally excluded (including 8 cases of anorexia nervosa) only 1 had an output as low as this. In many cases, however, especially in severe anorexia nervosa and myxoedema, subnormal levels were found. In mild anorexia nervosa 17-k.s. excretion was normal but decreased with protracted malnutrition. Repeated estimations in 1 case complicated by pulmonary tuberculosis showed an eventual decrease to 1.2 mg in twenty-four hours.

Simmonds's disease developed in 3 patients after severe post partum haemorrhage, in 1 case the 17-k.s. output was nil for the first four days of the puerperium and then increased gradually to 2 mg in twenty-four hours and remained at this level until the clinical signs of hypopituitarism became obvious. In a small series of patients estimations performed in the immediate period after normal delivery showed a decrease in excretion compared with pre partum levels but remained within the normal range.

Primary Testicular Failure.—In 7 eunuchoidal men with testicular atrophy 17-k.s. excretion was 5.5–11 mg in twenty-four hours. Estimations were also done in 14 young adults with poor development of secondary sex characters (8 had gynecomastia). Presumably no interstitial cells had been destroyed, because sexual maturity was attained later. In this group 17-k.s. output was 7–23 mg in twenty-four hours. The only inference to be drawn from this small series is that cases of testicular atrophy show a group tendency to a low normal 17-k.s. excretion which is absent in cases of delayed puberty. In the individual case a low figure has no diagnostic value, but a high normal value (over 15 mg) may be taken to indicate undisturbed testicular function.

3. Miscellaneous Conditions

Dwarfism.—In 13 cases of varying types of dwarfism associated with sexual infantilism 17-k.s. excretion was 0–11 mg in twenty-four hours. In 3 of these cases dwarfism was due to destruction of the pituitary gland by a craniopharyngioma, and the values were 0, 0.7, and 2.3 mg in twenty-four hours. In the 10 other patients the estimation was of no apparent diagnostic value.

Pituitary Tumours.—A normal result was obtained in 7 cases of acromegaly. The test was therefore of no value in confirming the diagnosis or in assessing the activity of the disease. In 7 cases of chromophobe adenoma of the pituitary gland the 17-k.s. excretion was 7.0–27.3 mg in twenty-four hours, but these values could not be correlated with the clinical evidence of endocrine function, the highest value was found in a woman with no endocrine abnormalities. In this group 3 women presented with amenorrhoea and obesity, and in them the 17-k.s. excretion was 7.0–22.5 mg in twenty-four hours.

Other Conditions.—Estimations were made in 9 cases of menstrual disturbances, 2 cases of pregnancy, 3 cases of thyrotoxicosis, 3 cases of aspermia or impotence, and

Fig. 2—17 K S excretion in cases in which suprarenal underaction was suspected: white squares, female; black squares, male.

1 case each of acne, hydatidiform mole, cutaneous striae, and gigantism. A patient with severe pre-eclamptic toxæmia of pregnancy excreted 2.6 mg of 17-K S in twenty-four hours. Excretion was normal in all the other cases, and in no instance did the estimation contribute to the diagnosis.

DISCUSSION

Correct interpretation of urinary 17-K S estimations obviously depends on the reliability of the method. In our experience the major cause of error has been inaccurate collection of urine samples. Since the result is expressed as output in twenty-four hours, a complete collection of urine over that period of time is essential. Unfortunately the importance of this is not always realised by patients and nurses.

Several factors other than endocrine disease may influence the 17-K S output. Excretion varies considerably with age, rising steadily from early puberty to a peak at the age of 25. It then declines with increasing age, slowly in the male and more sharply in the female, to reach a constant level in the mid-thirties, after which it decreases further in old age (Hamburger 1948). The output is diminished by about half in chronically ill, debilitated, or malnourished people (Forbes et al 1947). Impairment of liver function also leads to decreased excretion (Fraser et al 1941). Values above normal have been found on occasions in this laboratory in patients with simple obesity, carcinoma of the bronchus, and ankylosing spondylitis. Similar findings have been reported by Warren (1945) and Davison et al (1947). Hormonal therapy may influence 17-K S excretion; testosterone causes a definite increase, but methyl testosterone produces no significant change (Frame et al 1944). Deoxycortone does not seem to influence 17-K S excretion (Cuyler et al 1942). Administration of oestrogens usually diminishes the high output in virilism.

The most common use of 17-K S estimation has been to test for increased cortical function in cases of suspected adrenal tumour. The estimation is of no value in the diagnosis of a non-secreting adrenal tumour unless both adrenal glands have been destroyed, causing Addison's disease. Most of the secreting tumours of the adrenal cause a considerable increase in 17-K S output, but with some such tumours the 17-K S excretion has been reported to be normal. As Kepler and Mason (1947) have shown, tumours producing true virilism are associated with a considerable increase in 17-K S excretion, but, if the tumour gives rise to Cushing's syndrome without virilism, a normal 17-K S excretion is not uncommon. Thus a normal value for 17-K S output may be taken to exclude the presence of a secreting adrenal tumour if virilism is present.

The range of 17-K S output with adrenal tumours with virilism is very wide, varying from 100 to 2000 mg in twenty-four hours (Dorfman 1948). Amounts up to 100 mg in twenty-four hours may be found in patients with virilism due to simple hyperplasia, as in 1 case in the present series. In patients who excrete so much 17-K S differential estimation is of value, since the B fraction is relatively higher in the presence of a tumour than in simple hyperplasia.

As the present series shows, the aetiology of virilism is both variable and obscure, and 17-K S estimation has only a restricted value in diagnosis. Increased 17-K S output may be found in patients with virilism due to ovarian disease—e.g., arrhenoblastoma (Goldberg et al 1947)—where the adrenals appear normal. Virilism with adrenal hyperplasia may very occasionally be associated with a normal 17-K S output. Several workers have reported 'normal' or only slightly increased 17-K S excretion in cases of active Cushing's syndrome (Fraser et al 1941, Warren 1945, Escamilla 1949). From our own findings it is apparent that there is no relation

between the degree of activity of Cushing's syndrome and the 17-K S output, and that determination of the 17-K S excretion is of no value in differentiating Cushing's syndrome from obesity due to other causes.

There is sometimes uncertainty in the interpretation of a very low 17-K S output determined by the colorimetric method. The polarographic method is sufficiently specific to give nil readings on blank specimens without introducing correction factors, which makes the test more reliable in the diagnosis of adrenal insufficiency. In males with Addison's disease the production of testicular steroids may confuse the interpretation, but in hypopituitarism the test is of equal value in both sexes. Confusion may also result from decreased 17-K S secretion in severe anorexia nervosa or in myxoedema, but in the present series 17-K S excretion was seldom as little as that found in true adrenal or pituitary failure. This confirms the work of Fraser et al (1941).

In several conditions the 17-K S output proved of no diagnostic value. These include dwarfism (apart from hypopituitarism), acromegaly, chromophobe adenoma of pituitary, menstrual disturbances, hydatidiform mole, and asperma.

The 17-K S excretion is an indirect measure of only one type of adrenal activity. Its estimation has its use in the assessment of endocrine function, but as a diagnostic aid it is of value in only two types of endocrineopathy: it is a reliable test for adrenal failure, either primary or due to pituitary failure, and it also provides confirmatory evidence of cortical overaction in patients with virilism whether due to tumour formation or to cortical hyperplasia.

SUMMARY

The results of 17-K S estimations on 253 patients with suspected endocrine dysfunction are reviewed. Variations in the 17-K S excretion due to factors other than endocrine disease are discussed.

The estimation proved of great value in the diagnosis of Addison's disease and Simmonds's disease, and provided a reasonable guide to the presence of adrenal hyperfunction in cases of virilism. It was of no value in the differential diagnosis of Cushing's syndrome from other causes of obesity.

The test does not assist materially in the diagnosis of other endocrine diseases.

MILEMAN'S SYNDROME IN IDIOPATHIC STEATORRHOEA COMPLICATED BY REFRACTORY MACROCYTIC ANÆMIA

ALASTAIR ANDERSON

M.B. Camb., M.R.C.P.

CONSULTANT PHYSICIAN, ROYAL BERKSHIRE HOSPITAL, READING
LATELY RESIDENT ASSISTANT PHYSICIAN,
ST THOMAS'S HOSPITAL, LONDON

At times the bowel complaint is overlooked, the wasting weakness, paleness are what is noticed and are thought to be due to another than the true cause.—Samuel Gee (1888) *The Colic Affection*

In 1888 Gee described the stools of the "colic affection" and recognised that diarrhoea was by no means a necessary accompaniment "it may be that the patient voids daily but one large loose whitish looking stool." Nevertheless in practically every text book of medicine the student is invited to believe that increased frequency of defecation, at least in the morning, inevitably accompanies those anomalies of fat absorption comprising the sprue syndrome and not uncommonly called the fatty diarrhoeas. The truth is that, when diarrhoea does accompany the other classical qualities of the stool in the sprue syndrome—bulkiness, paleness, thinness, offensiveness—the recognition of sprue is practically unavoidable. But it cannot be emphasised too strongly that the symptoms of the sprue syndrome may include nothing referable to the gastro-intestinal tract, and that the stools may be normal in frequency and in macroscopic appearance. In these circumstances quantitative analyses of faecal fat, or preferably fat balance studies, will be the only method of establishing the diagnosis and of revealing the true cause of cases presenting with one or more of the complications of the primary disorder—disturbances of erythropoiesis and of calcium and phosphorus metabolism being the most important.

The case reported here is notable for the minimal signs of primary intestinal disease and for the great severity of the secondary manifestations.

CASE RECORD

A farm labourer's wife, aged 29, was admitted to St Thomas's Hospital on May 4, 1942, with twenty weeks' history of unproductive cough and loss of voice, and twelve weeks' history of dyspnoea on exertion. She thought she had lost weight in the previous few weeks. There was no hæmoptysis or other overt blood loss, oedema of the ankles or rashes. Her periods were regular. Her appetite was normal and her bowels were opened once daily, with stools of normal appearance. A week before admission a chest radiogram had shown no evidence of any lung lesion. Her sputum was free from tubercle bacilli. Apart from mastoidectomy in 1938 and appendectomy in 1940 her health had been good. Her mother, father, and nine siblings were alive and well, and a brother, who had had epilepsy from early childhood, died at the age of 34, the immediate cause of death being unknown.

On examination the patient was small and sallow looking and older than her stated age. Her temperature was 36.7° F., pulse-rate 80, respirations 20 per minute. Her mucosae were pale and her tongue was clean, shiny and pink. There was no cheilosis or dysphagia. The nails were normal, and there were no abnormal lymph nodes. The blood pressure was 105/65. There was no clinical enlargement of the heart. A soft systolic murmur was heard which was maximal in the second left interspace at the sternal edge and transmitted to the apex. There were no abnormal signs in the chest. The spleen was easily palpable and firm. It was doubtful if the liver was enlarged. No masses were felt by ocular fundi and the central nervous system were normal. Endoscopy of the nasopharynx showed evidence of a mild rhinoidal infection and chronic laryngitis.

Investigations.—A blood-count on May 5 1942 showed red cells 1,980,000 per c.mm. Hb (Haldane) 40%, colour index 1.01, white cells 2380 per c.mm. with a normal differential

count and reticulocytes less than 0.1%. A film of peripheral blood showed much anisocytosis and poikilocytosis, some polychromasia and two hemoglobinised megaloblasts. On May 7 the aspirated sternal marrow showed polymorphs 19.5%, lymphocytes 1.75%, monocytes 0.25%, eosinophils 1.75%, metamyelocytes 8.75%, neutrophil myelocytes 7.0%, eosinophil myelocytes 0.75%, transitional myeloblasts 0.5%, myeloblasts 0.75%, normoblasts A 8.0%, normoblasts B 8.5%, normoblasts C 8.25%, and megakaryoblasts 34.25%. The pathologist's report commented on the high proportion of megakaryoblasts, of which a third were hemoglobinised, and described the appearance as "typical of pernicious anemia." On the same day occult blood was found in the faeces. On May 8 a histamine test-meal was abandoned because the patient was unco-operative. On May 13 a blood-count showed red cells 1,590,000 per c.mm., Hb 31%, colour index 0.97, and icteric index 6. Occult blood was again found in the faeces.

Treatment and Progress—Pernicious anemia was diagnosed, and an initial intramuscular injection of 'Pernamon Forte' 20 ml was given.

May 18 1942 the patient was very pale and looked ill. Hæmorrhages were seen round both optic discs. A blood count showed red cells 1,460,000 per c.mm., Hb 30%, colour index 1.03 and reticulocytes 4.4%.

May 19 a blood transfusion of 1 pint was given, and a course of injections of pernamon forte 2 ml twice weekly instituted.

Further blood counts on May 21 (red cells, 2,120,000 per c.mm., Hb 41%, reticulocytes 5.2%), and on May 28 (red cells 1,860,000 per c.mm., Hb 42%, reticulocytes 5.3%) having shown that there was no satisfactory response to liver therapy, a further blood transfusion of one pint was given on May 30. Thereafter the position improved, and on June 11 the Hb had risen to 74%.

June 13 the patient complained of epigastric pain after food and was tender below the right costal margin. A barium meal, given on June 22, revealed an active prepyloric ulcer.

June 25 a blood-count showed red cells 4,100,000 per c.mm., Hb 84%, and colour index 1.01, and the patient felt very well. At this stage, owing to war circumstances she was discharged on pernamon forte 2 ml fortnightly, must ferri et ammonii cit 1 oz t.d.s., and Moulengracht's diet. In view of the refractoriness of the anemia, the persistence of a colour index greater than unity, and more significant, the coexistence of a radiologically demonstrated gastric ulcer, the previous diagnosis of pernicious anemia was considered to be almost certainly incorrect, but unfortunately there was no opportunity to investigate the case further at that time.

Follow up—During the first two years after her discharge the patient was seen at irregular intervals in the follow up clinic and her general condition remained fairly satisfactory. Her Hb level was well maintained between 94% and 110% on pernamon forte 2 ml fortnightly, which was reduced to 2 ml monthly after three months. Her colour index however remained persistently greater than 1. On two separate occasions she complained of soreness of her tongue, and examination showed it to be red and fissured, but this condition settled spontaneously. On Sept 3, 1942 (two months after discharge) she had an attack of diarrhoea, with up to ten motions in 24 hours. The stools were bulky and dark (she was still taking iron). This attack lasted three weeks and gradually subsided. A year after discharge low backache developed, of which the significance was not appreciated at the time. This persisted with intermissions and was from time to time accompanied by aching pains behind both knees. Apart from some discomfort on percussion of the spines between T6 and T10 and pain in the same area on extremes of extension and flexion, no abnormal signs were elicited and the knee joints remained clinically normal. Radiography of the spine at that time revealed no abnormality of either bones or joints. On Aug 2 1944, after two years' surveillance in the follow up clinic, the patient was returned to the supervision of her own doctor, who continued her monthly liver injections. Iron was omitted and having had no recurrence of epigastric pain the patient had reverted to a normal diet. On Aug 7 1946, a further two years later, she was again sent to the clinic being 4½ months pregnant, pale, and dyspnoeic. About three months previously her doctor had changed her liver prescription to 'Examen' 1 ml fortnightly and a blood-count showed red cells 4,350,000

per c mm, Hb 62%, and colour index 0.7. It was recommended that this dose of examen be doubled, and iron ('Fersolate' tab 2 b d) given in addition.

Readmission—The patient was readmitted thirty four weeks later, having had a stillbirth twelve weeks previously, at full term. She was complaining that the intermittent pain in her back had become more persistent and severe over the past twenty eight weeks, and there was now a similar pain across her shoulders and "a sort of pain" behind her knees and in her calves. Her legs felt weak and she could climb stairs only with difficulty. She had fallen on numerous occasions. Apart from these pains she felt very well. There had been no recurrence of diarrhoea. Her weight was steady.

On examination her skin was pale, but there was no pallor of her mucosae. Her tongue was normal and there were no abnormal lymph nodes, and no abnormal signs in the chest. The systolic murmur heard during her first admission was unaltered. Her apex beat was in the fifth interspace $3\frac{1}{2}$ in from the midline. The blood pressure was 105/75. The spleen was palpable 1 in. below the costal margin. The edge of the liver was not felt. Rectal examination was normal. The urine contained no abnormal constituents. The patient had a waddling gait suggesting a myopathy. There was a slight dorsal kyphosis with well marked lumbar lordosis. There was tenderness on percussion over the whole dorsal spine, but movements were full. Flexion of the lumbar spine was limited by pain. Other joints were normal. No abnormality was found in the central nervous system. Spondylitis ankylopoietica was tentatively diagnosed.

Investigations—On April 14, 1947, radiography of the pelvis and sacro iliac joints showed fractures of both pubic rami and general decalcification of the pelvis. There was poor definition of the left sacro iliac joint, but no definite change was seen. Radiography of the rest of the skeleton between April 16 and 23 showed pseudo fractures of the upper third of the shaft of the left fibula and of the posterior aspect of the shaft of the right tibia, at the junction of the upper and middle thirds of the right and left ulnae, of the axillary borders of both scapulae, and of the middle third of the right femur. No change was found in the lumbar or the dorsal spine. The radiologist reported that the appearances were those of Milkman's syndrome. On April 18 a blood count showed red cells 3,400,000 per c mm, Hb 76%, colour index 1.1, white cells 5400 per c mm, normal differential count, slight anisocytosis, haematocrit 36, mean corpuscular volume 106 c μ , mean corpuscular Hb 31 μ g, and mean corpuscular Hb concentration 29%. On April 24 a test-meal showed the presence of free hydrochloric acid. On April 29 the serum calcium was 9 mg per 100 ml, inorganic phosphorus 2.8 mg per 100 ml, and alkaline phosphatase 67 Shumway units per 100 ml (normal 2.2-3.6 units). On May 6 aspirated sternal marrow contained Ferrata cells 20%, megaloblasts 2.25%, normoblasts A 4.5%, normoblasts B 8.0%, normoblasts C 12.75%, myeloblasts 0.75%, neutrophil myelocytes 16.25%, eosinophil myelocytes 4.50%, basophil myelocytes 0.25%, metamyelocytes 11.25%, transitional cells 19.75%, polymorphs 11.75%, eosinophils 1.0%, lymphocytes 4.0%, plasma cells 0.5% and monocytes 0.5%.

Treatment and Progress—On May 9 1947, a course of proteolised liver (Hepamino $\frac{1}{2}$ oz t d s) was started by mouth. Between May 10 and 13 58% of the daily intake (50 g) of fat was absorbed. On May 11 the prothrombin index was 101%, dried faeces contained 53.4% of fat of which 55% was split. On May 27 a blood count showed red cells 4,560,000 per c mm, Hb 84% and colour index 0.92. Between June 10 and 13 41% of the daily intake of fat was absorbed. On June 12 the serum calcium level was 8.0 mg and inorganic phosphorus level 2.9 mg per 100 ml.

Diagnosis—Osteomalacia with Looser zones (Milkman's syndrome), due to idiopathic steatorrhoea and precipitated by the recent pregnancy.

Treatment was begun with high potency 'Ostelm' 50 000 units t d s, with calcium gluconate 2 teaspoonfuls daily.

Progress—After two weeks intensive treatment there was an important subjective improvement. The bone and joint pains disappeared, and the patient was comfortable in bed for the first time for nine months. On July 10, 1947, after a month's treatment, there was early calcification at all the fracture and pseudo fracture sites, with a generalised increase

in bone density. On July 30, the serum-calcium was 9.0 mg and inorganic phosphorus 4.8 mg per 100 ml, and radiography showed excellent callus at all the fracture sites, with normal mineralisation elsewhere. Meanwhile the anaemia had responded slowly to the oral liver, and by Aug 1 the Hb was 94%. The patient was discharged home the next day. During the whole of this second admission, and particularly after defective fat absorption had been found, the naked eye appearances of her stools were followed with interest and, although they were sometimes bulkier than normal and somewhat paler, they never, even distantly, approximated to the classic descriptions of the stools in sprue.

Follow up—Although the patient had been taught birth control methods before her discharge, she became pregnant again sixteen weeks after returning home. It was decided that this pregnancy should be allowed to continue without any alteration in her maintenance therapy, except that intramuscular injections of 'Hepostab Forte' 4 ml monthly was substituted for the Hepamino, which had become nauseating and iron (fersolate 2 tablets t d s) was provided in addition. During the whole of this pregnancy the patient felt extremely fit, and on repeated estimations her serum-calcium and serum inorganic phosphorus were within normal limits.

She was admitted to the obstetric ward on Aug 17, 1948, owing to anxiety about a residual pelvic deformity, and there, on Sept 5 after medical induction, a child weighing 4½ lb was born by high forceps delivery. The puerperium was uneventful, and mother and child returned home seventeen days later.

DISCUSSION

In the light of subsequent events it is particularly unfortunate that this patient was not induced to swallow a Ryle's tube during her first admission. A diagnosis of pernicious anaemia cannot be certain in the absence of histamine fast achlorhydria. This patient, however, before her premature but unavoidable discharge, provided circumstantial evidence that free acid was present when she developed a radiologically demonstrable gastric ulcer.

In pernicious anaemia the coexistence of a simple gastric ulcer is so rare as to cast the gravest doubt on one or other diagnosis. In this case a malignant ulcer, although a well recognised complication, was ruled out by the patient's subsequent progress. Free hydrochloric acid was demonstrated after a histamine test meal on her second admission, but by this time the underlying but unrecognised steatorrhoea had led to osteomalacia of the third degree and verging on the fourth (Albright et al 1946).

Cooke et al (1948), presenting the hematology of 41 cases of idiopathic steatorrhoea, showed two main groups on examination of the blood films. The first and smaller group presented a macrocytic picture, with well stained erythrocytes, closely resembling that of pernicious anaemia—there was, however, less poikilocytosis, and substantial numbers of target cells ("Mexican hat" cells) were present. In the second and larger group there was considerable variation in depth of staining, and in cell size, the smaller cells tending to be hypochromic and the larger normochromic. Poikilocytosis was moderate in this group, and target cells were seen in most cases. Out of 21 cases at initial examination, the colour index was greater than unity in 13, and in 8 of the 17 of these in which determinations were made the mean cell volume was greater than 105 c μ . The sternal marrow was examined in 17 cases, and in 4 of these the marrow was hypercellular, megaloblastic, and indistinguishable from that seen in pernicious anaemia. The peripheral blood in these cases was macrocytic and fell into the smaller peripheral blood picture group already described as closely resembling pernicious anaemia. The second and commoner type of marrow showed erythroblastic hyperplasia with a mixture of deformed iron deficiency normoblasts and large atypical erythroblasts. Attention has also been drawn to these large

throbasts by Innes (1948). They are smaller than globoblasts but larger than typical normoblasts, the amount of nuclear condensation is not so great as in a normoblast with comparable haemoglobinisation, and they have been described as "intermediate erythroblasts." This review of recent studies of the bone marrow and peripheral blood in idiopathic steatorrhoea emphasises the difficulty for the pathologist in differentiating that condition from pernicious anaemia by haematological examination alone. In the first place a minority of cases will be virtually indistinguishable, having a globoblastic marrow and macrocytic peripheral blood picture. It is true that there may be less poikilocytosis in a normally seen in pernicious anaemia, and a variable number of target cells may be present, but neither of these can be regarded as reassuring criteria for the pathologist. In the other and larger group, although the marrow is erythroblastic, very many cells are of the typical intermediate type and may be mistaken for globoblasts, leading to a diagnosis of pernicious anaemia, particularly if the colour index is greater than 1 and the mean cell volume is increased. Confusion becomes clearer if the patient has been treated with liver, because the bone marrow of pernicious anaemia treated with inadequate dosage of liver is commonly of the intermediate type.

The response to therapy is likely to raise suspicion of the correctness of a diagnosis of pernicious anaemia if the anaemia of idiopathic steatorrhoea is refractory to liver, and it is unusual to obtain normal maturation in these cases presenting with the intermediate erythroblastic type of bone marrow, although cases with a globoblastic marrow may develop into the intermediate type after liver therapy. In all cases there is usually a marked increase in the amount of haemoglobin and red cells in the peripheral blood—although seldom up to normal levels. Even after protracted and massive demonstration of liver the marrow contains large numbers of intermediate erythroblasts, and this defective maturation is reflected in the peripheral blood, where persistent abnormalities of the erythron lead to a high colour index (often greater than unity) and an increased mean corpuscular volume, even when, as in the present case, the haemoglobin has been raised to over 90%. In this case it will have been noted that the bone marrow was globoblastic on the patient's first admission, but a year later, after liver therapy throughout that period, it had become "normoblastic." Since the mean corpuscular volume was still 108 c μ , probably at least some of the "normoblasts" were in fact cells of the intermediate erythroblast type. Further evidence of erythron abnormality, even after treatment, is provided by increased erythrocyte resistance to hypotonic saline (McKee et al. (1948) made fragility tests on 18 cases of idiopathic steatorrhoea and found that, with one exception, their resistance was increased, and this increase was independent of the degree of anaemia. In 5 out of 18 cases, in which their treatment restored the number of red cells and Hb to normal, the resistance of the red cells was persistently increased. Since this finding obviously differs from that in pernicious anaemia, treated or untreated, in which there is normal resistance, it may serve as a method of distinction, and should be used wherever there is doubt. The same may be said for serum bilirubin level, classically raised in pernicious anaemia but normal or insignificantly raised in the anaemia of idiopathic steatorrhoea. But these points are only subordinate, because, whenever there is doubt, investigations must be directed to the bowel condition, even when, as in the present case, there is overt evidence of any anomaly in absorption of

although most cases of idiopathic steatorrhoea present obvious evidence of intestinal dysfunction—

increased frequency of passage of bulky pale frothy offensive stools—a considerable number have only occasional episodes of diarrhoea, between which they may have a normal bowel habit or even constipation, and a still smaller number may for years betray their underlying disorder by nothing more dramatic than isolated and infrequent attacks of diarrhoea mistakenly regarded as simple gastro enteritis. Such was the state of affairs in the present case. This is not surprising, for there is little evidence that steatorrhoea as such causes diarrhoea. Patients with idiopathic steatorrhoea and fluctuating periods of diarrhoea and constipation show no corresponding fluctuation in the amount of faecal fat. Further, it is usually possible with folic acid to produce a reversion to normal bowel frequency in patients with idiopathic steatorrhoea accompanied by diarrhoea, and fat balance studies before and after treatment commonly show no improvement whatever in fat absorption (Davidson et al 1947).

It is not unreasonable to suppose that, when diarrhoea develops in idiopathic steatorrhoea, it is symptomatic of some as yet unidentified part of the general deficiency pattern of this disease and is only coincidentally associated with an increased amount of faecal fat, both being but symptoms of the underlying defect in bowel absorption. The fact that folic acid may control diarrhoea in certain cases of idiopathic steatorrhoea with anaemia without producing a haemopoietic response suggests that it has at least two separate actions, the one concerned with bowel function, and the other with haemopoiesis (Davidson and Girdwood 1947).

In most institutions the investigation of suspected steatorrhoea must at present depend on quantitative analyses of faecal fat, but, since the amount of faecal fat fluctuates greatly—depending, among other things, on the daily intake of fat—and, when expressed in percentages, varies inversely with the amount of unabsorbed non fatty residue, many estimations must be made, with the patient on as standardised a diet as possible, before the results can be assessed. A far better method, where practicable, is that of fat balance estimation (Cooke et al 1946). In this test a percentage of absorption of less than 90% is abnormal. In the present case the percentage absorption was 58% on one occasion and 41% on the next. The aetiology of this patient's steatorrhoea has not been established. The only certain method of distinguishing between idiopathic steatorrhoea and fibrous pancreatitis is by duodenal intubation and estimation of the enzymal activity of the aspirated contents, and this has not been done. Secondary and less reliable assistance may be obtained from the glucose tolerance curve, which tends to be flat in idiopathic steatorrhoea in contradistinction to that obtained in fibrous pancreatitis. The curve was flat in the present case.

Although steatorrhoea probably does not of itself produce diarrhoea, it is responsible for deficiencies of all the fat soluble vitamins—A, D, E, and K (Albright and Stewart 1940). On her second admission there was no evidence of deficiency of vitamin K in our patient (prothrombin index 101%), but there were ample signs of hypovitaminosis D, for she had osteomalacia, aggravated by the calcium drain of her recent pregnancy but directly due to her steatorrhoea.

The usual variety of juvenile rickets is due to uncomplicated insufficiency of vitamin D, and this is also true of that form of adult rickets (osteomalacia) prevalent in China. Consequently these conditions respond to small doses of vitamin D. The same cannot be said for osteomalacia in the United States (Albright et al 1946) or in the United Kingdom. Here again hypovitaminosis D is the commonest cause, but defective absorption is responsible and steatorrhoea the reason, in rare cases of raised resistance to vitamin D (McCance

1947) are excluded, and far larger doses of vitamin D are needed to produce a therapeutic response. Albright et al (1946) have discussed the effects of hypovitaminosis D and the following summary analyses the features relevant to the present case

It will be noted that the result is a normal serum calcium level with a diminished serum phosphorus level. The body-fluids contain too little inorganic phosphorus for the level of calcium, and normal calcification is impossible. Osteomalacia results and, with it, increased osteoblastic activity leading to increased serum alkaline phosphatase. The findings in the present case at the second admission illustrate this type of osteomalacia: serum calcium 9.0 mg per 100 ml, serum inorganic phosphorus 2.8 mg per 100 ml, and serum alkaline phosphatase 67 Shinowara units (normal 2.2-8.6 units) per 100 ml.

Although hypophosphatæmic osteomalacia is the commonest form, the relative values of serum calcium and serum phosphorus depend on the parathyroid response to a lowered serum calcium level, which itself is due to defective absorption. If hyperplasia is lacking, a normal serum phosphorus level and a low serum calcium level—not infrequently down to tetanic levels—results. If the response is partial, both serum phosphorus and serum calcium levels will be reduced. In all cases the serum calcium and serum phosphorus levels will be below normal, and osteomalacia will result. Attention must be drawn here to the futility of estimating the serum calcium level alone when attempting to decide whether osteomalacia is present. Administration of vitamin D in sufficient dosage, provided the calcium intake is adequate, will restore calcium phosphorus metabolism to normal and cure the osteomalacia. This result was rapidly attained in the present case with high potency osteon 50,000 units t.d.s. and calcium gluconate 2 teaspoonfuls daily.

Finally, radiography in the present case revealed appearances variously described as Milkman's syndrome or multiple spontaneous idiopathic symmetrical pseudo-fractures. In this condition the radiograms show ribbon-like bands of translucency in otherwise normal bone, often symmetrical and chronic, unless treated appropriately. Attention was first drawn to them by Looser (1920) as occurring in osteomalacic states, and they are often referred to as Looser zones. He considered them to consist of areas of uncalcified callus within the bone brought about by a "mechanical irritation due to strain" and by "small local infractions" (Looser 1940). Milkman (1934) described a case in which the bone lesions were unresponsive to therapy, thus differing from the German cases and constituting a new disease. McCullough (1940), on the other hand, thinks that they occur in many unrelated bone diseases and merely indicate weakening or overloading.

Albright et al (1946) think that, though superficially similar lesions may appear in other bone conditions, Milkman's syndrome only occurs in osteomalacia. They base this conclusion on four considerations: (1) "the symmetrical ribbon-like zones of decalcification seen by X ray, and often occurring in otherwise normal appearing

bone, are characteristic of that disease and that alone", (2) "the serum calcium, phosphorus, phosphatase findings in most of the undoubtedly are those of osteomalacia", (3) "such patients respond to therapy based on the assumption that they have osteomalacia", and (4) "the histopathology is that of osteomalacia". They separate osteomalacia into four degrees: (1) "chemical osteomalacia with normal phosphatase", (2) "chemical osteomalacia with raised phosphatase", (3) "Milkman's syndrome", and (4) "advanced osteomalacia"—i.e., general skeletal demineralisation. They believe it justifiable to regard the radiological diagnosis of Milkman's syndrome to call attention to the fact that one can have underlying osteomalacia when the only X ray evidence is the ribbon-like zones of decalcification.

The tendency for the pseudo fractures of Milkman's syndrome to develop symmetrically and in particular positions—the femoral necks, the pubic and ischial bones, the upper third of the ulnae, the ribs, &c., and commonly the axillary borders of the scapulae—has aroused considerable interest. Looser believed that they occurred at points of stress or tension, and pointed out that such stresses are liable to be symmetrical. Le May and Blunt (1947), having analysed the sites of election of these pseudo fractures, find that there is a close correspondence between them and the anatomical position of arteries passing adjacent to the bone—e.g., the commonest site of all is the axillary border of the scapula, where the circumflex scapular artery winds round in close apposition to the bone. They believe that, if pressure of arteries in certain circumstances can groove normal bone, it is not remarkable that osteomalacic bone would be affected and that the "infractions" of Looser may be brought about in this way. This matter remains debatable.

SUMMARY

A case of occult steatorrhœa accompanied by grave disturbances of erythropoiesis and calcium phosphorus metabolism is described.

The difficulties of differential diagnosis between pernicious anaemia and macrocytic anaemia due to idiopathic steatorrhœa are discussed.

The mechanism of production of osteomalacia resulting from hypovitaminosis D, with special reference to the type known as Milkman's syndrome, is outlined.

The importance of fat balance estimations is emphasised.

The radiological appearance of Milkman's syndrome is described, together with a short review of the hypotheses relating to the sites of the pseudo fractures (Looser zones) characteristic of the syndrome.

Owing to war time dislocations this patient came under the care of several members of the staff of St Thomas's, and my grateful thanks are due to them for permission to publish this case and for many helpful suggestions and criticisms.

PRIMARY STREPTOMYCIN-RESISTANT TUBERCULOSIS IN A NEWBORN CHILD

SIMPLE METHOD OF ASSESSING STREPTOMYCIN RESISTANCE

UNIVERSITY OF EDINBURGH

THE readiness with which some strains of *Mycobacterium tuberculosis* develop resistance to streptomycin during a protracted course of treatment is now well known, but it is only beginning to be realised that streptomycin-resistant strains may, on rare occasions, be derived from patients before they have received any streptomycin (Cruckshank 1950). This possibility emphasises the necessity for routine testing of the streptomycin sensitivity of strains isolated before the inception of streptomycin therapy as well as during the course of treatment. The prognostic importance of this procedure is illustrated in the following case of primary tuberculosis in a young infant, from whom tubercle bacilli highly resistant to streptomycin were isolated before the start of streptomycin therapy. We are also describing a simple and simple method of determining the degree of resistance in such cases.

CASE RECORD

A female infant aged 11 weeks when admitted to the Royal Edinburgh Hospital for Sick Children on Aug. 4, 1948, was born at the Eastern General Hospital Edinburgh on Mar. 20 five weeks premature, the second of binovular twins and weighed 4 lb 3 oz at birth. She was breast-fed until the eighteenth day, when her mother, who had been running a remittent temperature since the eleventh day post partum, was suspected of having active tuberculosis. At that time the infant was thriving and weighed 4 lb 13 oz. She continued to thrive on a fresh cow's milk mixture and weighed 6 lb 1 oz. at 7 weeks. At 9 weeks she ceased to gain weight, though she still fed well and looked healthy for the next week. Her abdomen then became distended and examination revealed a greatly enlarged spleen and a moderately enlarged liver. In the last few days before her admission to the children's hospital she was feverish and taking her feeds badly.

Family History.—The child's parents were Irish. A miniature radiogram of the mother's chest taken during pregnancy was negative. She developed severe pre-eclamptic toxæmia in the thirty-first week of pregnancy and was admitted to the maternity unit of the Eastern General Hospital. On the tenth day of the puerperium she developed a remittent temperature and tachycardia; she had had a slight cough for several months and night sweating since the delivery of the twins but no physical signs of disease were found in the chest. The pyrexia increased and on the eighteenth day she complained of a pleuritic pain in the left chest. Clinical and radiological examination then showed tuberculous infiltration at the left apex and an effusion at the left base. The baby was thereafter kept apart from the mother who was transferred to a medical ward a week later. Repeated examinations of the mother's sparse sputum, including routine culture and one guinea-pig inoculation, were negative as were examinations of gastric washings, stools, urine and aspirated pleural fluid. Her general condition improved, but after five months in the medical ward tomograms still showed tuberculous infiltration of the left upper lobe and a small peripheral cavity. She refused artificial pneumothorax, and 46 weeks after the birth of her twins she returned to her parents' home in Eire. Streptomycin was not given at any time during her hospital treatment. She had since returned to her own home in Edinburgh, but has consistently refused to attend a tuberculosis dispensary for examination. The father, however, had attended twice, and showed no evidence of tuberculosis.

The other twin, a boy, developed a volvulus of the small intestine and died after an operation when 5 days old.

Condition on Admission.—Small thin baby weighing 6 lb 14 oz with poor muscle tone, and several pustules on the scalp and trunk. No cyanosis or dyspnoea. Radiography showed primary tuberculosis of the lungs (fig. 1). The abdomen was greatly distended with slightly dilated superficial veins over the upper part. The spleen and liver were greatly enlarged, both extended to 3 finger breadths below the costal margin and both were firm with a smooth surface. No tubercles were ever seen in the optic fundi. Red-cell count 3,200,000 per c.mm. Hb 72% white cells 16,600 per c.mm. A Mantoux test with O.T. 1 in 1000 was negative. Gastric washings did not show any tubercle bacilli on direct examination of concentrate smears but human type tubercle bacilli which proved to be highly resistant to streptomycin were grown on culture. Cerebrospinal fluid (c.s.f.) normal.

Treatment and Progress.—Streptomycin, 20 mg per lb body weight per day was begun three days after admission. Four hourly injections of 25 mg were given intramuscularly. The child fed well for her first six days in hospital and gained 1/2 lb. In the next few days her weight fell rapidly though she still fed well. Her weight fell 1 1/2 lb to 5 lb 14 oz in the second and third weeks in hospital and it then remained at about 6 lb for many weeks until a few days before her death. The Mantoux test with O.T. 1 in 1000, when repeated eleven days after her admission had become positive. She was afebrile for her first five weeks in hospital but later her temperature occasionally rose to 100°F. The c.s.f. was examined weekly and was always normal. Radiography of the chest a month after her admission showed diminution of the miliary mottling and some consolidation in the right upper lobe and eight weeks after admission the liver and spleen had become much smaller and radiography showed less pronounced mottling in the lungs but increased consolidation in the right upper lobe (fig. 2). Ten and a half weeks after the start of streptomycin therapy the dosage was changed to 50 mg eight-hourly until the course was stopped two weeks later after twelve and a half weeks treatment. During this last fortnight of therapy the streptomycin titre in the blood was estimated on several occasions: half an hour after injection blood streptomycin level was 16 µg per ml on two occasions and 32 µg per ml on one occasion; four hours after injection it was 16 µg per ml on one occasion, and eight hours after injection it was 8 µg per ml on one occasion and less than 2 µg per ml on another. The erythrocyte sedimentation rate remained raised throughout the illness varying between 32 and 43 mm per hour. A week after the end of streptomycin therapy gastric washings were collected on several occasions for examination for tubercle bacilli: the result was the same as that before the start of treatment, no tubercle bacilli being found on direct films, but tubercle bacilli of human type, highly resistant to streptomycin being isolated on culture. The child's condition deteriorated and she died eleven days after the end of the streptomycin therapy at the age of 25 weeks; her weight was only 5 lb 3 oz. No further radiological changes had taken place in the chest. Permission for a necropsy was not given.

BACTERIOLOGY

A culture of tubercle bacilli isolated from gastric washings only a few days before death was available.

Fig 1

Fig 2

Fig 1.—Radiogram of chest before start of streptomycin therapy showing miliary mottling of primary tuberculosis and some medial collapse of right upper lobe.

Fig 2.—Radiogram of chest eight weeks after start of streptomycin therapy showing diminished mottling in lung fields and massive consolidation of right upper lobe.

for comparison of streptomycin sensitivity with the original culture similarly obtained at the time of admission to hospital. During the twelve and a half weeks between the isolation of these two cultures the patient had received about 116 g of streptomycin, and it was hoped that a study of the organism might throw some light on the failure of the antibiotic to check the tuberculosis.

In the first instance both cultures were tested for streptomycin sensitivity by the Dubos method, which is routinely used in Medical Research Council trials. This method, which is widely applied, uses the detergent-containing medium of Dubos, in which, after one or more subcultures, the tubercle bacilli grow as a visible turbidity. A series of doubling dilutions of streptomycin is then added to bottles of the same medium, and, by a further subculture, the minimal dose required to inhibit growth is determined. The details of the test are given elsewhere (Medical Research Council 1948). Although the degree of streptomycin resistance of the great majority of strains of *Mycobacterium tuberculosis* can be demonstrated by the Dubos method, the test is of limited value, since the range of concentration of streptomycin, which usually varies from 0.03 to 6 μg per ml, may prove too narrow and the maximal concentration may not completely inhibit highly resistant strains. In the present case three separate tests on each specimen showed that there was no apparent inhibition of either of the patient's cultures, even by the highest concentration of 6 μg per ml of streptomycin. Since the control H37Rv was uniformly sensitive to 0.5 μg per ml, the relative degree of resistance in both cases was not less than twelve times that of the control. A sensitivity test with a wider range than that provided by the standard Dubos method for the estimation of high degrees of streptomycin resistance is therefore necessary in such circumstances.

Crofton and Mitchison (1948), by testing different colonies from the same culture from a case under treatment, have shown that there may be different degrees of resistance present. It is therefore essential to make the inoculum for any test truly representative by drawing the loop over a wide area of the primary culture, and we have adopted the precaution of emulsifying the specimen so obtained very thoroughly by an hour's slow mechanical shaking in a bottle with glass beads. But, even if the sampling is satisfactory, the method only gives an over all picture of the sensitivity or resistance of the patient's strain at the time of the test and no indication of its future state. It could not, for instance, discriminate between a large number of moderately resistant bacilli partially inhibited and multiplying slowly and a few highly resistant bacilli totally uninhibited and multiplying rapidly.

Holt and Cruickshank (1949) described a simpler and quicker sensitivity test for routine use in which cultures on slopes of Löwenstein-Jensen medium are compared with parallel cultures on the same medium in which

2-5 μg per ml of streptomycin has been incorporated. The streptomycin can be added either by mixing the medium before its solidification, with all loss of potency on heating, or by allowing the slope to absorb streptomycin solution uniformly surface while lying horizontally. Any culture grows on plain medium but not on the streptomycin-containing medium is regarded as sensitive. A few late colonies may appear on the treated slopes; these can be disregarded. A method using also as this one, reduces the risk, inseparable from that of liquid media, that resistant bacilli which have been comparatively scanty in the inoculum will to dominate the final result.

"VERTICAL DIFFUSION" STREPTOMYCIN SENSITIVITY TEST

One of us (J. E. T.) also had experimented with cultures on solid medium, using a method in diffusion of streptomycin from the base of a Löwenstein-Jensen slope. This "vertical diffusion method" is simple to use and gives not only a broad indication of sensitivity but also an indication of the number of resistant variants, which may have a considerable bearing on the degree of present and future resistance to streptomycin. Since it seems particularly appropriate to the type of case recorded in this paper the method is described in detail.

ESTIMATION OF STREPTOMYCIN SENSITIVITY OF VARIOUS STRAINS OF *Mycobacterium tuberculosis* BY VERTICAL DIFFUSION METHOD

Strain	Dubos method (μg per ml.)	Vertical diffusion method				
		Zones of inhibition with streptomycin in cm at 4 weeks to nearest 1/16 cm (averages)			No. of colonies in zones of inhibition at 6 weeks	
		1 μg per ml.	10 μg per ml.	100 μg per ml.	10 μg per ml.	100 μg per ml.
No. 1	1/2	1.75	3.25	Complete inhibition	0 & 1	0 & 0
No. 2	1/2	1.5	3	"	0 & 1	0 & 1
No. 3	1/2	1.5	2.75	"	1 & 1	0 & 0
No. 4	1/2	1	2.5	"	1 & 2	0 & 1
H37Rv	1/2	1.25	2.75	"	0 & 3	0 & 1
No. 5	1/2	0.5	2.25	"	0 & 9	1 & 3
No. 6	>6	Nil	1.5	"	Uncountable	55
No. 7	>6	Nil	Nil	Nil	"	Uncountable

The tests were performed in duplicate on all strains except 6 and 7 which were from the present case and thus two readings were obtained of the number of resistant colonies.

Method.—6 ml amounts of Löwenstein-Jensen medium are poured into 1 oz. screw capped vials and solidified as slopes in the usual manner. Any condensation water is decanted and 1 ml of streptomycin solution is then added to the bottle at the base of the slope in three strengths—1, 10, and 100 μg per ml. Such concentrations cover the range attainable by clinical dosage. The vials are then labelled and kept refrigerated until required.

For each test the specimen is concentrated—e.g., by Petroff's alkali or Jungmann's acid iron peroxide method—and loaded standard loopfuls are inoculated by stroking the entire slope of plain Löwenstein-Jensen medium and the streptomycin containing media, the "1" and "10" strength being essential in all cases, and the "100" concentration repaying inclusion, especially in cases of increasing resistance in the course of treatment. Similar cultures of the strain H37Rv are also made as controls. The bottles are incubated in the upright position.

After three or four weeks' incubation at 37°C confluent growths are seen on the control slopes, whereas the bottles containing streptomycin show zones of complete inhibition extending from the foot of the bottle and varying in extent with the dose of streptomycin and the sensitivity of the organism. Thus in an average case of sensitivity 1 μg per ml may cause inhibition on about a third of the slope, 10 μg per ml on about two thirds, and 100 μg per ml on the whole.

Fig. 3.—Vertical diffusion method of estimating streptomycin resistance. A single large resistant colony of the strain H37Rv is growing on a Löwenstein-Jensen slope at the base of which is a solution containing 100 μg of streptomycin per ml.

4. Löwenstein Jensen plate with gutter containing 100 μ g per ml solution of streptomycin. This shows the high degree of streptomycin resistance of strain 7 of *Myco. tuberculosis* from the case described compared with that of a sensitive control (H37Rv). Growth of control culture (above) is restricted to one edge of plate whereas resistant strain (below) is growing uninhibited up to margins of gutter.

From the fourth week onwards, however, a very few minute isolated colonies began to appear in the zone of inhibition, irregular in distribution but most numerous at the upper margin. The number of such colonies of streptomycin resistant variants tends to be small and fairly constant (see table). Fig 3 shows a bottle containing a single large colony of the strain H37Rv resistant to 100 μ g per ml of streptomycin. That they were truly resistant and not due to the streptomycin losing its potency was proved by testing the individual solution in the bottle for activity.

Streptomycin-antagonist Medium—Where the patient has already been on streptomycin therapy, culture of the infecting organism is often unsuccessful unless a streptomycin antagonist is added to the medium. We use Löwenstein-Jensen slopes to which 2 mg of cysteine hydrochloride per ml of the medium is added before pouring. During subsequent heating the powerful reducing action of the cysteine may bleach the lactate green with which the medium is coloured, but, when the bottles are stood with their caps screwed down, the colour becomes deeper in colour. When growth has been observed on the cysteine medium the organisms are inoculated into the streptomycin-containing bottles for subsequent sensitivity tests. By this method one specimen from a patient who had received streptomycin therapy for nine months was successfully grown after five negative results on the ordinary medium.

Bacilli—The accompanying table gives the results of the examination of several representative strains showing initial sensitivity to streptomycin, and in the strain from our patient which showed initial resistance to streptomycin. The extraordinarily high degree of resistance of the organisms isolated from our patient both before and during streptomycin therapy contrasts sharply with the free of resistance shown by all the other strains tested. Strain 6, obtained before the start of streptomycin therapy, was totally uninhibited by 1 μ g but sensitive to 10 μ g of streptomycin after incubation for 1 month, but with longer incubation resistant colonies became uncountable with 10 μ g, and 55 such colonies were present even with 100 μ g. In strain 7, obtained after the completion of 3 months' streptomycin therapy, resistant organisms had multiplied to such an extent that confluent growths were obtained at both 10 and 1 μ g as well as at 1 μ g after incubation for a month. It is noteworthy, that although the initial streptomycin resistance was so high it was considerably enhanced by 3 months' streptomycin therapy just as in the vast

majority of cases with little or no initial streptomycin resistance. The intense resistance developed is well shown in the Löwenstein-Jensen plate (fig 4). Strain 7 and the control strain (H37Rv) were streaked on the medium at right angles to a gutter containing a solution of streptomycin in a concentration of 100 μ g per ml. The plate was then sealed and incubated at 37°C for two months. The growth of the control culture was restricted to one edge of the plate, while the resistant specimen grew uninhibited up to the margin of the gutter on both sides.

DISCUSSION

It is unfortunate that most streptomycin sensitive organisms tend to become increasingly resistant to streptomycin when exposed to it, some strains show this tendency to a much greater degree than others. During the long course of treatment of tuberculous patients streptomycin resistance develops slowly and can seldom be demonstrated in the first month. Thereafter widely differing rates of development have been reported, but all are agreed that there is a rapid increase in resistance in the second month of streptomycin therapy. Several workers have shown that streptomycin resistance is very uncommon before the start of streptomycin therapy. Blattberg and Ehrhorn (1949) tested the streptomycin resistance of tubercle bacilli obtained from 39 patients before, during and after treatment with streptomycin 1 g daily for 90-180 days. Before the start of treatment none of the 32 strains tested was resistant to 2.5 μ g of streptomycin per ml. After 30 days' treatment no resistant strains were found. After 60 days 13% had resistant bacilli, after 90 days 29%, and after 100-120 days 45%. The proportion of resistant bacilli increased after cessation of treatment in 4 cases. Nevertheless, Pyle (1947) and others have shown that tubercle bacilli isolated from patients before the institution of streptomycin therapy do not have a uniform susceptibility to the bacteriostatic action of streptomycin. Youmans and Williston (1948) found that streptomycin resistant variants were obtained from 43½% of 57 strains of tubercle bacilli isolated before the institution of streptomycin therapy, and they believe that the isolation of streptomycin resistant variants before the beginning of, or early in the course of, therapy indicates the probability of development of resistant strains, and thus the prognosis.

The development of streptomycin resistant strains in the community which has recently been observed is probably caused, in the vast majority of cases, by infection from patients who have received streptomycin therapy and in whom the surviving tubercle bacilli have developed streptomycin resistance. Thus, the proportion of streptomycin resistant tubercle bacilli in the community will be likely to increase in proportion to the greater use of streptomycin. This accommodation of susceptible organisms to antibiotics by the development of resistant strains is a feature of antibiotic therapy in general, the increasing prevalence of penicillin resistant *Staph. aureus* being a notable example.

The likelihood that cases of tuberculosis which show initial resistance to streptomycin will become increasingly prevalent emphasises the need for routine sensitivity tests. To be of value the results of any sensitivity test should be available before, or at least at an early stage in, streptomycin treatment, and the ideal plan would be to test the diagnostic cultures of cases on entry to hospitals or sanatoria and to record the findings for reference. The vertical diffusion method described here offers a simple and rapid test suitable for routine use in small laboratories, and by indicating resistant variants as well as the general level of sensitivity it may suggest the probable response to streptomycin. It is particularly suitable for the type of case which we have described because it reveals the full extent of the initial resistance.

and the hopelessness of even massive therapy which might succeed in a border line case

We believe the case recorded here is of particular interest and rarity, because the streptomycin resistance observed before the start of streptomycin therapy must almost certainly have been a primary resistance and not the more common acquired resistance produced in the infecting strain by streptomycin therapy. In May, 1948, when this infant was infected, streptomycin had not become available for general hospital use in Scotland, the meagre supply being still allotted to research units. It therefore seems extremely unlikely that infection could have been contracted from anyone harbouring tubercle bacilli rendered streptomycin resistant by streptomycin therapy. It is unfortunate that no tubercle bacilli were isolated from the infant's mother, who was the probable source of infection since it would have been of great interest to compare the streptomycin resistance of her infecting organisms with that of the organisms isolated from her infant.

SUMMARY

A case of miliary tuberculosis in a young infant yielded cultures of *Mycobacterium tuberculosis* showing a high degree of primary resistance to streptomycin. The probable source of infection was the mother and neither mother nor baby had previously received any streptomycin.

Resistant variant bacilli are usually very scanty in cultures made before the start of streptomycin treatment, but in the present case they were numerous.

A simple vertical diffusion streptomycin sensitivity test is described which demonstrates higher degrees of streptomycin resistance than does the standard Dubos test, and also indicates the number of resistant variants present.

The prognostic value of a streptomycin-sensitivity test on organisms isolated before the inception of streptomycin therapy is emphasised, and a plea is made for the routine performance of a simple initial test such as the vertical diffusion test described.

For the bacteriology of this paper grateful acknowledgment is made to Prof. T. J. Mackie for his constant encouragement and advice and to Dr. J. P. Duguid for his suggestions.

THROMBOTIC "HYDROCEPHALUS" IN INSULIN THERAPY

JOHN DONNELLY

M.B. Lpool, D.P.M.

ASSISTANT PHYSICIAN

E. J. RADLEY SMITH

M.S. Lond., F.R.C.S.

VISITING NEUROSURGEON

CANE HILL HOSPITAL, COULSDON, SURREY

THROMBOSIS of the cerebral veins and sinuses has long been recognised and extensively reported. Gowers (1893) classified it into primary and secondary types according to the absence or presence of local septic lesions. The primary type, though comparatively rare, occurs in a wide range of diseases associated most often with the extremes of life, it occurs in marasmic and cachectic conditions, in protracted debilitating illnesses, in tuberculosis and typhoid, in conditions giving rise to increased concentration and increased coagulability of the blood (as in dehydration due to persistent diarrhoea), in blood disorders (such as leukaemia and chlorosis), and with low blood pressure, and it may present as part of the clinical picture in

thrombophlebitis migrans. The secondary type is associated with septic conditions of the face, scalp, and nasopharynx, and of the paranasal and mastoid air sinuses.

In the past decade attention has been directed to primary cerebral thrombosis by its increasing recognition as a complication of pregnancy and the puerperium (Symonds 1931, 1937, Martin, 1941, Martin and Sheehan 1941, Stansfield 1942, Kendall 1948). Kendall reviewed the literature on cerebral vascular catastrophes in this connection since Ménère's paper in 1828.

Symonds (1931) suggested the name otitic hydrocephalus for the syndrome of increased intracranial pressure, with a cerebrospinal fluid (C.S.F.) of normal composition, caused by thrombosis of the superior longitudinal (sagittal) sinus arising as a complication of otitis media. McAlpine (1937) proposed toxic hydrocephalus as a more inclusive title, since the identical picture was caused by infection in the nasal passages; he described five cases in which a "cold" appeared to play a significant aetiological rôle.

The term hydrocephalus usually implies a gross excess of C.S.F. either within the ventricles or in the subarachnoid space. Though the symptoms of thrombotic "hydrocephalus" are similar to those of hydrocephalus, it is doubtful if there is a great excess of C.S.F. Two sets of findings point to this conclusion: (1) where either ventriculography or encephalography has been done, as in some of McAlpine's (1937) cases and in two of those reported here, neither dilatation of the ventricles nor an undue amount of supratentorial air was demonstrated; and (2) the striking relief of the symptoms, and the reduction of pressure to within normal limits by the removal of small amounts of C.S.F.—in none of the present cases was more than 30 ml. removed at any one puncture. However, since there probably is an excess of C.S.F. sufficient to cause the increase in pressure within the theca, and since this arises as a sequel to thrombosis of the venous sinuses, the title thrombotic "hydrocephalus" is aetologically accurate and clinically descriptive.

We describe here three cases of thrombotic "hydrocephalus" occurring as complications of insulin therapy, in which several factors may favour thrombosis.

FIRST CASE

Mrs. A., aged 42, was admitted on Oct. 18, 1948, with ideas of persecution, and a recent history of auditory hallucinations. She was evasive in her answers but in a clear state of consciousness.

Insulin treatment began on Nov. 17, and on 100 units of insulin she passed into her first coma on Nov. 23, almost immediately she had a major epileptiform convulsion. After immediate interruption with glucose by tube feed she regained consciousness with no residual signs. On Dec. 14 she had a secondary hypoglycaemia but rapidly recovered on taking glucose by mouth. On Dec. 15 and 18 recovery from coma was slower than usual. On Dec. 22—the 18th coma—she developed laryngeal spasm, with cyanosis, and breathing afterwards was depressed. Nikethamide and oxygen were administered. Recovery of consciousness was slow in spite of intravenous glucose, and she was drowsy for the rest of the day. Her temperature at 6 P.M. was 100.8°F, pulse rate 84, and respirations 22. Next day she appeared fairly well, but treatment was not resumed until Dec. 28. On Dec. 29 she complained vaguely of numbness of face, hands, and legs. Her speech was slower than normal for her. On Jan. 1 she appeared to have slight spastic dysarthria but no objective signs were found. Treatment was suspended, but in spite of symptoms of numbness and stiffness of the left side of the face, and numbness of both hands and of the right leg and foot, no sensory or motor impairment was found on Jan. 9. Treatment was therefore continued next day. On Jan. 12 she vomited her nasal feed and recovered slowly after intravenous glucose. She seemed to have a little difficulty with her speech. Though she remained active, pleasant, and sociable there was little improvement in her psychotic symptoms, and it was therefore decided to try combined insulin and E.C.T.

electroconvulsive Therapy—Electric convulsions were in d during the 32nd, 33rd and 34th comas (Jan 22, 24, 25). On Jan 26 she was more lethargic, she answered questions normally, but her speech was more dysarthric, and gait rather stumbling, and when she was asked to maintain her arms outstretched with her eyes closed, her right arm dropped downwards and outwards. She was disoriented for, saving the date was Oct 22. Over the next two days became more drowsy, she could be aroused to answer questions but was irritable. No papilloedema was found. Lumbar puncture on Jan 28 produced clear c.s.f. under a pressure of 180 mm. 20 ml. of c.s.f. was removed containing lymphocytes, protein 20 mg per 100 ml, chloride 760 mg per 100 ml. Lango and Wassermann reactions were both negative. Within an hour the patient began to improve, no longer drowsy and answering questions quite brightly. Jan. 29 she continued to improve, but on Feb 3 she began to become drowsy again and by Feb 7 she was in the same state as on Jan 28. Lumbar puncture produced clear c.s.f. under a pressure of 300 mm and unchanged in position.

Examination of the blood showed red cells 3,540,000 per c.mm., white cells 9000 per c.mm., Hb 66 per 100 ml, or index 0.94. The differential white cell count was normal.

Progress—Over the next month she exhibited the same features, i.e., increasing drowsiness, irritability and disorientation, which was relieved temporarily by lumbar puncture. The c.s.f. was always normal, there was a normal knee-jerk response and the physical signs were limited to slight weakness, dysarthria, slight differences in the arms, slight stiffness in gait. The plantar responses were normal throughout. The c.s.f. pressure gradually fell on Jan 17 it was 270 mm., on March 1 260 mm., on March 23 220 mm., and on April 12 130 mm. Radiography of the skull showed no abnormality.

Electroencephalography—Dr C. C. Evans, of Belmont Hospital, on Feb 25 reported as follows: "Alpha rhythm about 8 cycles per second and tends to be unstable. Slower frequencies, mainly in the theta range but sometimes in the delta range, are seen throughout the record in all areas but with maximal amplitude in the parietal areas. The abnormality is observed more in the transverse electrode position than in the anteroposterior. There is no significant asymmetry. There is a paroxysmal tendency. This record does not suggest a cortical lesion but rather a diffuse deep-seated disturbance, but the E.E.G. can throw no light on the underlying pathology."

Ventriculography (E. J. R. S.) showed that there was no dilatation, asymmetry, or displacement of the ventricular system.

Follow up—The only residual physical symptom is the stiffness of the face and hands. She has complete amnesia of the period from 1943 until the end of March, 1949, when increased pressure was disappearing.

Thrombosis of the superior longitudinal sinus was suggested on increasing drowsiness, increased intracranial pressure with a normal c.s.f., gradual recovery after repeated lumbar puncture, and a normal ventriculogram. The thrombosis was probably due to intimal tearing. The thrombosis was probably due to intimal tearing either from the effects of insulin, or from the increased intravenous pressure produced by the spontaneous fit on Nov 23, or from the laryngeal spasm. Subsequent severe cyanosis on Dec 22. Dehydration must be considered an important factor, because through insulin treatment the patient lost much fluid by sweating.

The first symptoms and signs appeared on Dec 29—six days after the spontaneous fit and seven days after the laryngeal spasm—but they did not increase until the induction of electric convulsions on Jan. 22–25, after which they increased rapidly. Moreover, the c.s.f. pressure was 180 mm on Jan 28 and 300 mm on Feb 7. Probably the early symptoms were due to thrombosis in the cerebral veins but the electric convulsions led to extension of the clot to the sinus or to a new thrombus in that vessel, obstructing the absorption of c.s.f. The pressure returned to normal 70–80 days.

The residual lesions are those which first appeared, suggesting that thrombosis of the veins led to permanent damage of the cortex.

SECOND CASE

Miss B. aged 26, was admitted on April 4, 1949, with schizophrenia.

Treatment—On April 11, 15, and 19 three electric convulsions were induced and on April 21 insulin treatment, starting with 20 units was begun. On April 22 and 25 E.C.T. was given in the evening the patient having recovered eight or nine hours earlier from the insulin administered in the morning. On April 29 she had the first insulin coma on 140 units during the seventh treatment. On the morning of May 6 she did not pass into coma on 220 units and in the evening she was given a further electric convulsion, during which a deep cyanosis developed, but she recovered normally. On May 7 insulin 240 units was injected, and the patient was very restless until at 9.30 A.M., in the stage of sopor, she had a strong spontaneous epileptiform convulsion. The hypoglycaemia was immediately interrupted, and she had fully regained consciousness by 9.50 A.M. At noon she felt very well. At 4 P.M. she complained of an intense headache, especially in the frontal region felt dizzy, was unsteady on standing, and became drowsy. There was slight papilloedema of both discs and the retinal veins were engorged more on the right than on the left. There was gross peripheral defect in the fields of vision, more on the right than on the left. The pupils were moderately dilated and reacted sluggishly and with small excursion to light and accommodation. No diplopia, nystagmus, or paresis of the ocular muscles, no other cranial nerve defect observed. Tendon reflexes on the right side, in both arm and leg, were exaggerated compared with the left, abdominal reflexes were absent, and the sense of passive movement in the great toe was defective on the left side.

Lumbar puncture produced clear c.s.f., pressure 280 mm. Pressure on the left jugular vein produced a rapid rise in the manometer reading, but pressure on the right vein caused scarcely any rise. Pressure was slowly relieved to within normal limits, examination of the fluid next morning showed protein 20 mg, glucose 72 mg, and chloride 730 mg per 100 ml.

Progress—After removal of the fluid the patient rapidly improved and the headache was relieved, persisting longest at the vertex. Her drowsiness disappeared with the headache. Her temperature was 98°F and pulse rate 80. On May 8 she was free from headache in the morning. Blurring of the discs, variable abdominal reflexes and tendon reflexes exaggerated on the right compared with the left were found. During the afternoon the headache began to return, and she was unsteady on her feet.

Lumbar Puncture—On lumbar puncture on May 8 the level of the c.s.f. rose abnormally slowly to 90 mm and showed good fluctuation with coughing. Compression of the right jugular vein produced no rise, but compression of the left produced an extremely slow rise to 150 mm with a very slow fall on relaxation. The c.s.f. contained protein 30 mg, chloride 735 mg, and glucose 70 mg per 100 ml. On May 9 there was no change in the clinical condition. Lumbar puncture yielded clear c.s.f. under a pressure of 230 mm. A Queckenstedt test gave a normal response on the left and an equal but much slower rise on the right. The fluid showed no cells, protein 20 mg, chloride 710 mg, and glucose 70 mg per 100 ml.

Progress—On May 11 she complained of severe headache and a rushing noise in the head and ears. On May 12 she appeared more stuporose, had difficulty in comprehension, and complained of headache and of throbbing in the ears. Papilloedema and altered reflexes were found as before, but there was also diminished hearing on the right side with impairment of air and bone conduction. No signs of inflammation were found in either ear.

Lumbar Puncture—On May 12 the manometer reading rose very slowly, taking over a minute to reach 80 mm. Pressure on alternate jugular veins produced no change in the level, but bilateral compression yielded a slow rise to 150 mm and an equally slow fall on relaxation. Coughing produced a sharp rise and fall. The c.s.f. contained a fair number of red cells, one lymphocyte and protein 50 mg per 100 ml. These unusual findings from the Queckenstedt test were attributed to a block probably at the foramen magnum, and the increased amount of protein in the c.s.f.

seemed to support this view. Further, for the two days following the puncture the pulse rate, normally about 80, fell to 60.

Progress—With the administration of 25% magnesium sulphate enemas the noises in the ears gradually disappeared and the headache and mental symptoms diminished. During the next week the improvement was maintained and the headache decreased, but the papilloedema persisted.

Electroencephalography—On May 17 Dr C C Evans reported a mild non-specific abnormality throughout the record. There is no evidence of a focal lesion. This would suggest that the lesion, if present is deep and centrally situated rather than near the surface of either hemisphere.

Lumbar puncture on May 21 yielded clear c.s.f. under a pressure of 140 mm, with only a slight difference between the Queckenstedt responses. The c.s.f. was normal, with protein 25 mg.

Ophthalmoscopy (Mr Maurice Whiting) on May 21 showed slight bilateral papilloedema, but the swelling was not above the retinal level.

Encephalography by Dr F Reitman at Netherne Hospital on June 9 showed a normal ventricular system, no dilatation or distortion, and no undue amount of supracortical air.

Follow up—The patient's condition appears to be stationary. The papilloedema has almost disappeared, her tendon reflexes are exaggerated on the right, and slight diminution in the peripheral field of vision of the right eye persists. Mentally there is no significant change.

Venous sinus thrombosis was diagnosed on the epileptiform convulsion, followed within a few hours by severe headache, increased intracranial pressure associated with normal c.s.f., papilloedema persisting for some weeks, and altered tendon reflexes. The diagnosis of a cerebral tumour was excluded by the subsequent course of the illness.

It is thought that a partial block occurred at the foramen magnum, the temporary increase in protein and fall in pulse rate to 60 apparently justifying this supposition. The increased c.s.f. pressure suggests that the superior longitudinal sinus was involved. The pressure returned to normal limits within three or four weeks.

THIRD CASE

Mrs C, aged 28, was admitted on Oct 13, 1948, with schizophrenia. She was mute and negativistic at times, and preoccupied with auditory hallucinations.

Treatment—Between Jan 7 and Jan 24 6 convulsions were electrically induced, and insulin treatment was begun on Jan 28. The first coma, on Feb 5, occurred on 160 units during the 8th treatment. Three days later, after fifteen minutes of her 3rd coma, the patient had a spontaneous epileptiform convulsion. Coma was interrupted with glucose by nasal tube and she was fully awake at 12.15 P.M., appearing physically normal. Insulin therapy was continued with no unusual features until her 34th coma on March 23 when she vomited the entire nasal feed. Next day extreme restlessness was a feature of the coma, and intravenous interruption was necessary. On the evening of March 25 she complained of not feeling well and treatment was interrupted. On the 26th she seemed to have a lump of the left leg.

As she did not improve mentally treatment was started again on April 6. E.C.T. was given during coma, producing a major fit. This was repeated on April 7, but only a tonic spasm developed. Insulin alone was continued until April 18, when an electric convulsion was again induced during coma. Combined shocks on April 19 and 20 produced only tonic spasms. No more treatment was given.

Progress—At first she was very restless, but over the next ten days she gradually became more withdrawn, lethargic and ultimately stuporose. On May 2 a lumbar puncture was attempted, but, though the theca was entered, the needle was withdrawn because of the patient's struggles. She had bilateral extensor plantar responses. On May 3 she was more rational than at any time since admission but she was amnesic for at least her stay in hospital. She was slightly dysarthric and walked with a limp swinging the left leg.

Lumbar puncture yielded clear c.s.f. under a pressure of 240 mm. A Queckenstedt test was indefinite. 20 ml of c.s.f. was removed. "Cells" one lymphocyte occasional

red cells. Protein 30 mg per 100 ml, no excess of globulin chloride 760 mg, glucose 65 mg."

Central Nervous System—On May 4 the patient had blurring of the nasal margin of left disc, with engorgement of the right retinal veins, but, apart from the dysarthria, no abnormality of the cranial nerves was observed. Hoffmann's signs were present in both arms, and the tendon jerks on the left were much exaggerated. In the legs the knee and ankle jerks on both sides were extremely brisk, the left more so than the right, and both plantar reflexes were extensor. She was less amnesic and less disoriented.

Progress—On May 6 she complained of a strained feeling over the frontal region, there was papilloedema of both discs, the reflexes were still very brisk, especially on the left. The left plantar response was definitely extensor and the right was doubtful. Lumbar puncture produced clear c.s.f. under a pressure of 160 mm. On May 7 the limp had disappeared and she was less coöperative, the papilloedema was less but the other signs were unchanged. On May 9 lumbar puncture produced normal c.s.f. under a pressure of 120 mm. Queckenstedt test normal.

Electroencephalography (Dr Evans) on May 17 showed a bilateral generalised abnormality which is non-specific and of moderate degree. Groups of slow frequency, mainly of the theta range, are seen throughout the record. This suggests that the lesion, if present, is probably deep and centrally situated, rather than near the surface of either hemisphere. Patient not very coöperative, and no further localisation is possible.

Progress—On May 20 the papilloedema had subsided, and the reflexes in the arms were not so exaggerated, but the left continued greater than the right, while in the legs the reflexes were still very brisk, the left more marked than the right. The left plantar response was extensor and the right doubtful. The patient still complained of the strained feeling in the frontal area.

Ophthalmoscopy (Mr Whiting) on May 25 showed temporal pallor on the right and some slight optic atrophy on the left.

Follow up—The patient is amnesic for her stay in hospital but can remember everything from the time she "came round" after puncture on May 2. She is rational and active but shows no inclination to think about the future. Her leg reflexes are exaggerated, and the left plantar response remains extensor.

Thrombosis of the superior longitudinal sinus was diagnosed on increased intracranial pressure with normal c.s.f., papilloedema, weakness in both legs, and bilateral plantar extensor responses. The initial neurological signs—limp and headache—suggest that the initial lesion was in a superior cerebral vein and spread later to the superior longitudinal sinus.

FACTORS PREDISPOSING TO THROMBOSIS

Anatomy

There are usually eight superior cerebral veins draining into the inferolateral aspect of the superior longitudinal sinus on each side (O'Connell 1934). An anterior group passes upwards and slightly backwards, but a posterior group passes upwards and forwards, making the direction of flow partly against that in the sinus. There is therefore in the posterior veins a tendency to stasis, which is accentuated when the patient lies a long time supine or when the pressure within the sinus is increased. Both these factors occur in the puerperium and in insulin therapy.

Increased Intravenous Pressure

Batson (1940) showed that blood from the pelvis and the legs may, when the intra-abdominal and intra-thoracic pressure is raised, pass by the vertebral veins to the intracranial sinuses. The vertebral veins, as they ascend, form a plexus which communicates not only with all segmental areas of the body but also with the basilar, sigmoid, and occipital sinuses (Brash and Jamieson 1943). Increased pressure within the abdomen and thorax, combined with the muscular contractions which take place in parturition and in epileptiform fits, will cause both decreased outflow from the cranial sinuses owing to the rise in pressure in the jugular veins and redirection of the venous return greatly augmented by

the muscular contractions, to the cranial sinuses. This may well overdistend the thin walled cerebral veins and thereby tear their endothelium (Kendall 1948).

Changes in Blood vessel Walls

At several necropsies after Sakel's insulin treatment changes in the blood vessels have been found, mostly in the arteries but sometimes in the veins and capillaries. Though in most cases all the coats of the blood vessels have been affected, the greatest damage has fallen on the endothelium (Ferraro and Jervis 1939a and b, Kastein 1938, Gralnick 1941), as shown by proliferation of the intimal cells, which are swollen and show changes in the cytoplasm and nuclei.

Thrombosis secondary to these changes has often been noted, it may affect veins of all sizes, and Kastein (1938) described a case of thrombosis of the superior longitudinal sinus.

Other evidence of changes in the vascular walls includes ischaemic degeneration of the glomerular arterioles and capillaries (MacKeith and Meyer 1939), small hemorrhages by diapedesis through the vessel walls, and alteration in the permeability of the blood (CSF, barner (Kingsley and Freed 1941)). It is therefore suggested that, as a result of alterations in nutrition, the intimal cells undergo changes, usually reversible, which may either in themselves lead to thrombosis or, in the presence of increased intravenous pressure, render the wall more susceptible to small tears.

Changes in Blood

The injection of insulin is given at 7 A.M., and hypoglycemia proceeds until the coma is interrupted usually three or four hours later. During this time many patients lose much fluid through profuse sweating and excessive salivation. Dehydration and therefore concentration of the blood (Whitby and Britton 1946), especially of the cells and proteins (including fibrinogen), are likely to result. Since 30-50 treatments are administered, the patient is exposed for a considerable time to these factors.

FORMATION AND SITE OF THROMBUS

The thrombus may take a long time to become large enough to cause symptoms or clinical signs. In the puerperal cases the symptoms have come on 4-137 days after parturition (Stansfield 1942). The intervals between the spontaneous hypoglycemic convulsion and the onset of symptoms in the present three cases were 36 days, about 6 hours, and 45 days.

The formation of the thrombus is supposed to start with a small lesion of the intima, which may be a change caused in the endothelial cells by insulin (as described above), a tear due to a rise in pressure in the superior longitudinal sinus (as postulated by Kendall 1948), or a combination of both. Platelets, fibrin, and leucocytes are next deposited, forming a nucleus—a grey thrombus—on which other blood elements are laid at different rates. If a vein is affected, the blood flow through it is slowed, eventually the lumen is occluded perhaps suddenly, and a red thrombus is formed. The process may then extend towards and involve the superior longitudinal sinus. Various types of thrombus in the sinus have been described: multiple small mural clots (Symonds 1937), a layer of clot lining the wall without occluding the lumen (Gowers 1893), a long thrombus attached to the wall only at one end (Martin and Sheehan 1941), a thrombus occluding the lumen of the sinus but present only in the anterior or the posterior portion of the vessel (Martin 1941), or a clot filling the whole sinus.

An aseptic clot soon becomes organised and canalised, with the re-establishment of the venous pathway, but the time taken depends on the type and size of thrombus. The symptoms will be relieved in this way or by the development of a collateral circulation.

PRODUCTION OF HYDROCEPHALUS

Excess of CSF may be caused by either increased formation or decreased absorption.

The superior longitudinal sinus is triangular in cross section, with the apex below. The superior cerebral veins enter the lower part of the sinus. At its superolateral angle the sinus communicates with the lacunae laterales, into which project arachnoid villi, from which CSF passes by osmosis into the lacunae. Therefore thrombosis along the superolateral angle of the sinus will block the entrances of the lacunae and raise the pressure of the CSF. Canalisation of the clot will restore the connection between the lacunae and the sinus. Before this happens the removal of excess CSF by lumbar puncture cures the hydrocephalus.

Thrombosis in the lower part of the sinus, if at all extensive, is likely to block the openings of the cerebral veins and so raise the intracranial tension. Then, unless an adequate collateral circulation develops, residual permanent damage due to cortical softening is likely to ensue in spite of repeated lumbar puncture.

Experimental attempts to produce hydrocephalus by thrombosis of the longitudinal sinus in young dogs (Beck 1944) have met with little success, but in a few cases fullness of the retinal veins developed. In dogs, however, the venous circulation is different and the collateral vessels can apparently cope easily with the blockage. Presumably in man, unless a large proportion of the villi are obstructed, those that remain not obstructed may be able to compensate for the disturbance.

SIGNS AND SYMPTOMS

Focal Signs

Thrombosis of a cerebral vein gives rise to local signs which depend on the part affected. Unless other channels dilate to drain the area, softening of the cortex may ensue, with permanent damage. In insulin therapy, as in the puerperal cases, various symptoms have been reported: paræsthesia, monoparesis and hemiparesis, dysarthria, aphasia, and amaurosis, most of which clear rapidly (Spencer 1948). In three personal cases, including the present case 1, the patients complained of persistent numbness of the face and of the fingers of one or both hands. Read et al (1939) reported a case of hemiplegia following insulin therapy which cleared up leaving a permanent left Hoffmann sign, left facial pîresis, and exaggerated reflexes. Though many of these symptoms and signs are due to the hypoglycemia, some of them, especially those persisting for a considerable time after interruption of therapy, are no doubt due to vascular disorders.

Epileptiform fits are a common but not invariable accompaniment of venous thrombosis, often occurring as presenting signs. Martin (1941) suggests that if the superior longitudinal sinus is occluded before the vein, convulsions are less likely, owing to the opening up of the collateral circulation, or alternatively that the absence of convulsions may be due to the gradual onset of the obstruction.

In insulin treatment major epileptiform convulsions are not uncommon in the early stages—i.e., within 100 minutes of the injections. Focal lesions following shortly after these are rare, and the fits must be attributed to the effects of hypoglycemia. We suggest that these convulsions may initiate the thrombosis by producing small lesions in the endothelium of the veins or the sinus.

Signs of Increased Intracranial Pressure

Headache is considered to be very constant and early (Kendall 1948) and may be generalised or localised. In the present three cases frontal and vertical headache was intense in one, one patient complained of a "strained feeling" in the head, and the third did not complain (though she may have had a headache). Papilloedema

may or may not be present in one of the present cases it was absent, and in the other two it was slight or moderate

The mental state varies also. Many patients are alert in spite of severe papilloedema, &c., but all stages of impairment, from lethargy through drowsiness to stupor and coma, have been reported. In psychotics the mental picture may be confusing. Vomiting is often absent.

Cerebrospinal Fluid

A marked and protracted increase in pressure of C.S.F. almost certainly indicates thrombosis in the superior longitudinal sinus. The composition of the C.S.F. is normal, and there is no increase in the amount of protein or in the white cell count, if bleeding has occurred red cells may be found.

DIAGNOSIS

Sinus thrombosis is unlikely to be confused with many conditions. Cerebral hæmorrhage and embolism have a more dramatic onset, and a cause for embolism can often be found. Subarachnoid hæmorrhage and meningitis can be excluded on the C.S.F. findings. Cerebral tumour presents the main difficulty and ventriculography may be necessary.

Thrombosis of the lateral sinus occurs most commonly with infection in the middle ear, and extension to the longitudinal sinus is relatively uncommon. The Queckenstedt test applied to diagnose occlusion of the lateral sinus is unreliable (Woodhall 1936). In thrombosis of the longitudinal sinus even less reliance can be placed on it, owing to the extensive collateral circulation (O'Connell 1934). In the present series there was a normal finding in case 1, no significant differences in case 3, and in case 2 the responses varied greatly as recorded above.

TREATMENT

Since a clot obstructing the entrance to the lacunæ laterales may become organised, with re-establishment of a lumen, repeated lumbar puncture, to remove the unabsorbed fluid and to relieve the pressure until this is achieved, is the rational method of treatment. The speed with which the headache and the drowsiness were eased by lumbar puncture was remarkable in two of the three cases, but the effects were temporary. As the days pass, the height of the pressure falls gradually to normal.

In all thrombotic conditions the use of anticoagulants is now recommended to prevent further spread, none of these patients were so treated, but nevertheless all made a good recovery.

Where cases present with repeated fits sedation is strongly indicated, especially since each convulsion would worsen the condition. Although each of these patients had a spontaneous convulsion during hypoglycæmia, none has shown a tendency to epilepsy since the conclusion of treatment, in spite of the absence of anti-convulsant therapy.

Little can be done, or indeed appears necessary, for residual symptoms due to local venous thrombosis. Recovery, if it takes place, proceeds uneventfully.

PROGNOSIS

Most cases of primary venous thrombosis of the dural sinuses are associated with other diseases which are themselves often fatal. The mortality rate in the puerperal cases, which appear the most closely related to those reported here, has been calculated by Kendall (1948) to be about 30%, but he considers that wider recognition of the thrombosis will lower this figure considerably. We have been unable to trace any published records of thrombotic "hydrocephalus" complicating insulin treatment of psychotics diagnosed during life, but the necropsy reports do indicate that the condition may have passed unrecognised, and we suggest

that among the deaths attributed in the past to "hypoglycæmic encephalopathy" may have been some due to thrombotic "hydrocephalus."

Residual effects due to damage of the cortex may persist, but recovery, when it takes place, seems generally to be complete. Numbness of the face and hand, slight differences in reflexes, and slight optic atrophy, none of which inconvenience the patient, have remained as permanent effects in one or other of the present cases.

DISCUSSION

In these three cases the thrombosis was associated with epileptiform convulsions, spontaneous and induced. The combination of electric convulsions and insulin is a well recognised therapy that may produce results where either alone is ineffective (Sandison and McGregor 1942, Barahona Fernandes and Polonio 1946, Freudenberg 1947, Sargent 1947).

In a case described by Kastein (1938), thrombosis of the superior longitudinal sinus was discovered at necropsy after a course of insulin therapy in which the patient had an epileptic fit. In his case and in ours, convulsions, spontaneous or induced, developed during the course of hypoglycæmic treatment. The intervals between the spontaneous fits and the onset of clinical manifestations varied but made it likely that in two cases at least the convulsions were an ætiological factor rather than an indication of the thrombosis.

Though we emphasise the importance of the fits we do not suggest that the convulsions alone are responsible for the thrombosis. Electric convulsions are a routine treatment in mental disorders, yet neurological lesions are rare, and such as have been reported are attributed to hæmorrhage or to embolism. We therefore postulate that in insulin therapy there are produced conditions eminently conducive to thrombosis: (1) the endothelium of the blood vessels suffers changes which alone may be sufficient to initiate thrombosis but which will in any case render the venous intima more liable to damage from overdistension during a convulsion, (2) the hypoglycæmia may induce a fit and thus increase the intra-venous pressure, and (3), if a lesion has developed, stasis and hæmoconcentration will favour the development of thrombosis.

The occurrence of three cases within so short a period suggests that the combination of electric convulsions and insulin renders the patient more liable to thrombosis of the cerebral veins and sinuses, and reinforces the conclusion that the fits, however caused, are of ætiological significance.

SUMMARY

Thrombotic "hydrocephalus" is suggested as the name for the clinical syndrome arising from thrombosis of the superior longitudinal venous sinus. Three cases of this syndrome arising as a complication of insulin therapy are described.

Factors predisposing to venous thrombosis are examined, and the site and formation of the venous thrombus are discussed. The production of "hydrocephalus" by thrombosis of the longitudinal sinus is examined with particular reference to anatomical and experimental findings.

The symptoms of thrombosis of the superior longitudinal sinus are briefly presented, and the differential diagnosis, with particular attention to Queckenstedt's test, is discussed.

The suggestion is made that convulsions are of ætiological importance, particularly when associated with the changes produced by insulin therapy.

We wish to thank Dr A. Walk, medical superintendent, Cane Hill Hospital, for permission to publish the cases here described, and Dr C. Dax and Dr L. Minski for facilities for radiological and electroencephalographic investigations.

ASSISTANT
PATHOLOGIST

THE MIDDLESEX HOSPITAL, LONDON

WE report here two cases of severe postirradiation bone-marrow depression complicated by bronchopneumonia which showed, post mortem, considerable organisation

Case 1—A man, aged 59, was admitted on Jan. 13, 1949, with six months' history of a generalised painless enlargement of superficial lymph glands. No other abnormality was found. A blood-count on Jan. 14 showed Hb 102%, white cells 6900 per c.mm. (neutrophils 71%, lymphocytes 22%, monocytes 6% eosinophils 1%).

Biopsy of an axillary gland showed a giant follicular lymphoblastosis with areas of rapid growth suggesting lymphosarcomatous change.

A ray therapy was begun on Feb. 15, a strip field technique being used, and was completed on March 9, 1949. White cell counts showed 2100 cells per c.mm. on March 9 and 900 per c.mm. on March 14. The patient exhibited no notable symptoms or signs of this considerable leucopenia, and unfortunately a differential count was not done then.

March 16 the total white cell count was still only 1000 cells per c.mm., and the patient developed pyrexia for the first time, his temperature rising to 104°F the following day and never falling entirely to normal before he died. Treatment with penicillin 100,000 units four hourly was begun on March 18, when he had a purpuric rash in the skin, more marked at points of pressure and tending to occur especially at sites of injection. Examination of his chest revealed no abnormal physical signs, but a chest radiogram on March 23 showed consolidation in the left upper and right mid zones. The following day the purpura had increased and the patient had severe epistaxis. A blood count on March 24 showed Hb 63%, white cells 2300 per c.mm. (neutrophils 74%, lymphocytes 18%, monocytes 7%, eosinophils 1%) and platelets 6000 per c.mm. The clotting time was 4 minutes and bleeding time longer than 15 minutes. The patient was transfused with two pints of fresh blood and his general condition improved, haemoglobin rising to 80% but the pyrexia continued although the dosage of penicillin was increased on March 25 to 250,000 units four hourly and streptomycin 0.5 g. was given four hourly.

March 28 a blood-count showed Hb 68% white cells 2000 per c.mm. (neutrophils 58%, lymphocytes 40%, monocytes 2%) and platelets 510,000 per c.mm. On this day there were gross signs of consolidation in the left upper zone of the chest anteriorly and in the right mid zone posteriorly. Radiography showed no change in the last five days.

March 29 the sputum gave a profuse growth of coagulase positive *Staph. aureus* and α haemolytic streptococci.

On March 31 the patient was transfused with a further two pints of fresh blood when his general condition was deteriorating rapidly.

April 4 the purpura had again increased, and signs of heart-failure had appeared, the physical signs of consolidation in his lungs remaining the same.

April 6 the patient died, the total white cell count having fallen to 840 per c.mm. twenty four days after the known onset of his granulopenia.

Necropsy—The body was that of a well developed elderly man with numerous petechial haemorrhages scattered over the skin surface. Internally, enlarged mediastinal lymph-glands up to 1 in. in diameter were all that remained of the previous generalised glandular enlargement. Only the changes in the lungs with which we are particularly concerned, will be mentioned here. Each pleural space contained about a pint of amber fluid, with thickening of the pleural surfaces. There was widespread almost confluent, consolidation of both lungs, sparing only parts of the lower lobes. On section the upper lobes resembled lobar pneumonia in its later stages, except that the cut surface was rather moister. Many portions of the lung sank in water.

Section of lung from case 1 showing advanced organisation of fibrinous exudate in alveoli ($\times 85$)

Histology—The great majority of the alveoli contained exudate in the process of organisation, only occasional dilated air-containing alveoli being present (see figure). Recognisable fibrin, often hyaline, occupied some of the air sacs though most were filled by young fibrous tissue. No bacteria were seen and only very occasional polymorphs. Moderate numbers of mononuclear cells often with large and irregular nuclei were present. Diagnosis: fibrosis of lungs follicular lymphoblastosis.

Case 2—A girl, aged 18, had attended the radiotherapy department of Bristol Royal Hospital on Sept. 30, 1948, with three months' history of a swelling of the left side of the neck, followed by a sore throat and the appearance of a small gland in the left supraclavicular fossa. At that time she had been found to have a mass of enlarged matted glands in the left side of the neck from the mastoid process down to the sternoclavicular angle. Biopsy had shown lymph gland with extreme lymphoid hyperplasia and loss of normal architectural pattern consistent with lymphosarcoma or lymphatic leukaemia. X-ray treatment had been given to the neck from Oct. 4 to Oct. 15, 1948, total dosage of 1500 r to both sides of the neck. Six weeks later the glands had recurred, and a chest radiogram had shown a left pleural effusion. Radiotherapy to neck and left axilla had been started again on Feb. 1, 1949, and treatment completed seven days later. The patient had then come to London and been admitted to the Middlesex Hospital on May 2, 1949.

On admission she complained of cough and dyspnoea on exertion and examination revealed a generalised superficial

painless lymphadenopathy, and signs of a left pleural effusion. A blood count showed Hb 100%, white cells 3600 per c mm (neutrophils 32%, lymphocytes 45%, monocytes 3%).

X ray treatment was suspended after only six days because the white cell count fell rapidly, but it was begun again on May 16 1949.

May 20 the sternal marrow showed extensive infiltration with lymphocytes (which constituted 94% of the total nucleated cell count of 196,000 per c mm) which had taken the place of the normal marrow tissue. These findings strongly suggested lymphatic leukaemia or lymphosarcoma. X ray treatment was continued, and the lymphadenopathy subsided rapidly, the patient's general condition being satisfactory, with a white cell count of 5000-8000 per c mm.

July 13 a pustule appeared on the right cheek, from which coagulase positive *Staph aureus* insensitive to penicillin and sensitive to streptomycin was isolated. Radiotherapy was again withheld.

July 15 the patient's temperature rose to 105°F with the maturation of the skin lesion, and a blood-count showed Hb 57%, white cells 2000 per c mm (neutrophils 1%), and platelets 50,000 per c mm. The patient was transfused with one pint of fresh blood. Treatment with penicillin 50,000 units four hourly had been begun on July 13, and, when the granulopenia was found by this blood count, the dosage was increased to 500,000 units four hourly, and streptomycin 0.5 g six hourly was given in addition.

July 17 radiography showed the pleural effusion to remain the same, and there were rounded opacities in the right second and third intercostal spaces.

July 19 spontaneous bruising beneath the left clavicle and a small petechial hæmorrhage on the back were found. At the right lung base were many coarse râles and a loud pleural rub. The patient became progressively more ill, jaundiced, and died on July 23, 1949.

Necropsy—The body was that of an intensely pale and slightly jaundiced girl, with numerous petechial hæmorrhages over the front of the chest, and enlarged glands visible in the neck. Internally, the lymph glands of the neck, mediastinum, and abdomen were all enlarged up to 1 in in diameter, and there was some enlargement of the liver and spleen. The left pleural space contained about 3 pints of bloodstained fluid, rather less on the right. The left lung was collapsed from pressure of the effusion, and its pleural covering was thickened and contained numerous small hæmorrhages. The right lung was firm as if consolidated, though slightly nodular on palpation, and its pleura was thickened, roughened, and in one or two places adherent to the chest wall. On section the lung resembled a lobar pneumonia in the stage of red hepatization, though moister and less uniform.

Histology—Some alveoli were packed with red cells, others were filled with a fibrin network or albuminous fluid, and in others the fibrin was being invaded by young fibroblasts. Occasional large clumps of bacteria buried in fibrin were seen, especially in the exudate covering the pleural surface. Only very rarely were polymorphs seen, but many large mononuclear cells were present, and in places the alveolar lining cells were enlarged to form a conspicuous layer. Towards the periphery of the lung were some normally aerated alveoli. Most of the bronchioles had lost their epithelial linings and contained fibrin and mucus. Diagnosis: lymphatic leukaemia, post irradiation granulopenia, and confluent hæmorrhagic bronchopneumonia, with early organisation.

DISCUSSION

References to the lung changes in granulopenia are scanty. Those we have consulted report commonly a hæmorrhagic bronchopneumonia with or without necrosis of the lung (Rotter 1925, Schaefer 1926, Hueber 1930). Some workers have found a pulmonary oedema (Morgan and Detweiler 1939, Tragerman and Goto 1939), and only infrequently has any chronic inflammation been noted. Baltzer (1926) states that in one of his cases there was hypertrophy of connective tissue and of alveolar epithelium. In the pneumonia of granulopenia an intra-alveolar fibrin network has been described by Empey and Proeschner (1932) and Schwager (1938). The patients in these cases, reported before the general use of antibiotics in the therapy of granulopenia, survived generally less than ten days.

We regard the lung changes seen post mortem in both our cases as examples of almost confluent bronchopneumonia as modified by granulopenia and antibiotics. The presence of bacteria and polymorphs usually indicates the inflammatory origin of a fibrinous exudate. Although few were seen in the lungs of our cases, all the features being taken into account, there was no danger of confusion with certain non-inflammatory conditions in which a fibrinous exudate enters the lung alveoli, such as uræmic pneumonia (Domach 1947). In this condition a passive transudate associated with heart failure is unusually rich in fibrinogen, a result possibly of the action of uræmic blood on the vessel walls, and masses of fibrin subsequently organised to fibrous tissue, fill the alveoli. Although this condition has been called uræmic "pneumonia," the absence of inflammation is an essential feature.

The polymorphs are generally believed to play a major part in the resorption of fibrin in the process of resolution. In our cases the fibrosis of the lungs can reasonably be attributed to the granulopenia.

Thrombocytopenia may have contributed to the hæmorrhage into the lung alveoli but was of relatively short duration. The term "agranulocytosis" has been purposely avoided here because it implies the complete absence of circulating polymorphs and is rare in its fully developed form. It seems that the resorption of fibrin can be interfered with by a reduction of granulocytes to the levels seen in these cases and short of complete agranulocytosis.

In the past, agranulocytosis or severe granulopenia has usually been fatal within a short time. With recent advances in chemotherapy we can expect to see more patients with associated bronchopneumonia surviving long enough for organisation to occur in the lungs, and for fibrosis of the lung to be recognised as a serious complication of granulopenic pneumonias.

We wish to thank Prof B W Windeyer, Prof A Kekwick, and Dr A Willcox for permission to publish notes of these cases, and Prof R W Scarff for his help and advice.

PREVENTION OF HÆMOLYSIS DURING FREEZING AND THAWING OF RED BLOOD-CELLS

A U SMITH

M B, B Sc Lond

From the National Institute for Medical Research, Mill Hill, London

FROZEN and freeze dried serum and plasma can be used therapeutically after storage for many months or even years.^{1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20} By contrast, whole blood or separated blood cells can be stored in vitro only at temperatures between +2°C and +8°C and for no longer than 4 weeks before transfusion.^{1,2,8,9,17,19,20} So far no method satisfactory for use on a large scale has been described for preventing the hæmolysis which occurs during freezing and thawing. Thus, Luyet's technique¹⁰ of freezing thin films of blood at -196°C, or Strumia's method¹¹ necessitating rigid temperature control of the frozen blood at -3°C, are mainly of academic interest, while the cells which survived freezing and thawing in the experiments of Griffiths et al.⁶ had increased fragility. The purpose of this communication is to report the action of glycerol in preventing hæmolysis due to freezing

and thawing Glycerol preserves the motility of spermatozoa¹²⁻¹⁴ subjected to low temperatures. It has also been used in experiments on the preservation of viruses^{11,18} and sarcoma cells.² With red blood corpuscles glycerol in low concentrations (3% approx.) has often been used as a hemolytic agent.² It was surprising, therefore, to find that in heparinised guinea-pig blood or rabbit blood mixed with equal volumes of semen diluents composed of buffered glucose saline solutions containing 10%, 20%, or 30% of glycerol, the corpuscles appeared microscopically unaltered in shape and size after a few minutes and after 1 hour at room temperature. The samples were then frozen at -79°C, and 1 hour later thawed at -40°C. The tubes containing final concentrations of 5% glycerol showed considerable hemolysis, whereas with 10% and 15% glycerol there was little hemolysis and the corpuscles were neither crenated nor obviously swollen.

A series of experiments was then carried out with samples of heparinised rabbit blood diluted with equal quantities of mixtures of glycerol in Ringer's solution, and glycerol in 0.85% NaCl. The results showed that with final concentrations of 10% or 15% glycerol the blood could be stored for 7 days at +2°C without appreciable hemolysis. After freezing quickly to, and storage at, -79°C for 5 minutes, 1 hour, 18 hours, 3 days, 4 weeks, 6 weeks, and 3 months, and subsequent thawing at -40°C, most of the red blood corpuscles survived and were unaltered in shape. The results with 5% or 20% glycerol were less satisfactory. Control samples diluted with Ringer's solution or 0.85% NaCl showed almost complete hemolysis on thawing. After cooling glycerol treated blood to -79°C slowly during 30 minutes or 1 hour, the red cells were slightly less well preserved.

The process of hemolysis during freezing and thawing of blood without glycerol, and its prevention in the presence of glycerol have been studied under the microscope,¹³ and were illustrated in a film shown during a symposium on the Freezing and Drying of Animal Cells, held at the National Institute for Medical Research in June.

In these preliminary experiments only one specimen of human blood was tested. 0.5 ml samples were diluted with equal volumes of 30% glycerol in Ringer, to give a final concentration of 15% glycerol, and then frozen at -79°C. When thawed after 2 hours, 24 hours, 1 week, 2 weeks, and 8 weeks, the red cells appeared little altered microscopically, and on centrifuging the colour of the supernatant fluid indicated only a slight degree of hemolysis. It remains to extend the *in vitro* work on human material and to investigate the behaviour of red cells so stored when reintroduced into the blood stream.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Pneumonia

PNEUMONIA was discussed at a meeting, on Dec 16, of the section of epidemiology and State medicine of the Royal Society of Medicine.

Dr W. H. BRADLEY, president of the section, pointed out that during the past thirty years both notifications and deaths had decreased, the death rate had begun to fall even before 1938, when chemotherapy was introduced.

Dr J. G. SCADDING discussed the classification of pneumonia in the light of knowledge concerning aetiology. He distinguished first the various aspiration pneumonias, including hypostatic, terminal, and postoperative conditions, and then subdivided the broad group of acute specific pneumonias according to their several aetiological agents. The bacterial pneumonias due to pneumococci, haemolytic streptococci, staphylococci, Friedlander's bacillus, and the tubercle bacillus, each had distinctive clinical features. The virus pneumonias could be subdivided into (1) those where bacteria were also concerned, as influenza and measles, and (2) those due to viruses alone, including psittacosis, ornithosis, and other unidentified pneumotropic agents. Pneumonias due to rickettsiae, such as Q fever, and to fungal and plasmodial causes were much less common.

Dr Scadding thought that aspiration pneumonias, which might occur in bronchitic subjects or after an acute upper respiratory infection, were often confused with virus pneumonias. The main characters of virus pneumonias were prominent constitutional, rather than respiratory, symptoms, lack of response to penicillin, normal leucocyte count, and a radiographic opacity whose distribution was neither segmental nor lobar. The cold agglutinin titre might be high. At Hammersmith Hospital, London, during the winter of 1949-50, aetiological agents were sought in 110 cases of pneumonia. In 46 cases no pathogenic agent was found, though mouse inoculation of sputum was not practised at first. Pneumococci were identified in 20 cases, staphylococci in 10, and the tubercle bacillus in 4. Serological evidence of influenza B was found in 11 cases, and high titres of cold agglutinins in 10. Of the 27 cases in which agents could not be identified even before chemotherapy was begun, 18 had segmental or lobular changes, 10 being in bronchitic subjects and 4 following an upper respiratory tract infection.

Prof. C. H. STUART HARRIS described investigations carried out in Sheffield in the winters of 1947-48 and 1948-49 which were designed to clarify the relation between influenza and pneumonia. Epidemiologically these two winters were different, in the first there was no influenza epidemic, whereas between February and April, 1949, there was a sharp outbreak of influenza A. In the first year, 85 cases of pneumonia or bronchitis were investigated bacteriologically and for evidence of influenza virus, and in the second period, between January and April, 1949, 95 cases were similarly studied. The age distribution in the two series was similar except that there were more subjects over the age of 65 in the second (influenza) period, and during this time the number of females studied was also higher.

Only 2 sporadic cases of influenza A were detected in the first year, but during the epidemic period 30

strains of virus A were recovered, and positive serological results were numerous. Of 17 fatal cases of pneumonia, 9 yielded virus and 6 staphylococci as well. Of the 53 non fatal cases of pneumonia investigated during the epidemic, 11 showed rises of influenzal antibody during their progress, and another 9 had on admission high titres of antibody indicating recent virus infection. Pneumococci or staphylococci were both recovered from the sputum in the virus positive cases. Only in the staphylococcal cases did the clinical evidence suggest a synergic virus bacterial relation. The types of pneumococci concerned did not differ significantly in the two years, but in the whole period 75% of 117 strains fell into types I-VIII. Professor Stuart-Harris referred to the low carrier rates in normal people for these types except type III, the rate was, however, higher in the immediate environment of cases of pneumonia due to these organisms. He suggested that carriage of pneumococci and preceding non-bacterial respiratory infection were both concerned in the genesis of pneumonia.

Dr B P MARMION described the results of an examination of 690 sera received during 1949-50 at the Central Public Health Laboratory, Colindale, from all over the country, and from cases of pneumonia at the Hammer Smith and West Middlesex hospitals. Clinically the cases were grouped as influenza (112), lobar pneumonia (108), bronchopneumonia (83), atypical pneumonia (322), and pyrexia of unknown origin (P.U.O.) (65). 27 cases of influenza were positive for virus B, and so also were 15 lobar pneumonias and 6 bronchopneumonias, 51 atypical pneumonias, and 8 cases of P.U.O. The influenza B cases were grouped in time between the end of January and the beginning of May, 1950. Q fever antibodies were found in 23 cases, clinically, 18 of these were atypical pneumonia, 2 influenza, and 3 P.U.O. Serological evidence suggestive of psittacosis was obtained in a few cases in all clinical categories. Cold agglutinins in titres exceeding 1 in 128 and *Streptococcus M G* agglutinins in titres exceeding 1 in 40 were found in 11 cases of bronchopneumonia and in 67 of the atypical cases—a total of 9% of all specimens from cases of pneumonia.

Dr BRADLEY questioned Dr Marmion regarding the *Streptococcus M G*, which is a non-haemolytic streptococcus first recovered from the lung or sputum from cases of atypical pneumonia in the U.S.A. Dr MARMION said that sera from cases of atypical pneumonia contained both agglutinins and precipitins for the *Streptococcus M G* but would also fix complement in the presence of normal tissue suspensions. Dr F O MACCALLUM pointed out that the *Streptococcus M G* had not been isolated in Great Britain, and also referred to the recent discovery in the U.S.A. of a new antigenic type of influenza virus unrelated to either virus A or B.

Dr PERCY STOCKS spoke of the statistician's three nightmares: hypertension, heart disease, and the influenza pneumonia conglomerate. It had been decided to continue to classify influenza with the group of acute respiratory diseases rather than with the virus diseases.

Dr STANLEY BANKS drew a parallel between the fall in incidence of the streptococcal diseases and of the pneumonias.

Dr R E SMITH appealed to clinicians to define their cases of pneumonia more carefully and to withhold chemotherapy from the benign cases now seen in adolescents and children, he felt that the severity of pneumonia in this group had greatly lessened even before the introduction of chemotherapy.

The meeting registered approval of the present classification of pneumonia from the standpoint of notification, and disapproval of any change at present to include atypical pneumonia in the notifications.

Reviews of Books

The Diagnosis of Salmonella Types

F KAUFFMANN, M.D., chief of the International Salmonella Centre, Copenhagen Springfield, Ill. Charles C Thomas Oxford Blackwell Scientific Publications 1950 Pp 58 16s 6d

THIS book is a practical guide to bacteriological methods by which a few experts, principally in Denmark, England, and the U.S.A., have separated a single bacterial genus into 198 species. To the physician it matters little which of these, unless it be *Salmonella typhi*, infects his patient. To the epidemiologist, however, this multiplicity presents ways of tracing infection which have on occasion proved useful, though limited in application by the fact that at one time and place the majority of salmonella infections are due to one or two species. Lastly, to the bacterial geneticist this genus and the serological interrelation of its species offers an almost untouched field.

Those who intend to distinguish the species of salmonella must have this book, but despite the clear and workmanlike exposition we doubt whether the tyro, with no other aid, will get far, for there is an art as well as a science of bacteriology. The "average" bacteriologist will be grateful to Dr Kauffmann but also glad that he can call on a Salmonella Reference Laboratory to unravel his tangled skeins.

Worth & Chavasse's Squint

(8th ed.) T KEITH LYLE, C.B.E., M.CHIR., F.R.C.S., surgeon and medical officer in charge, orthoptic department Westminster branch, Moorfields, Westminster and Central Eye Hospital London Bailière, Tindall, & Cox. 1950 Pp 319 35s

Worth's classical *Squint*, an easily read statement of fact, went through six editions under the hand of its begetter. The seventh edition was entirely revised by Bernard Chavasse, under whose hand it became much more complicated. Many foundered in their attempts to assimilate its new ideas of the binocular reflexes and their physiological basis, its chapters on comparative anatomy, and the teachings of Sherrington and Pavlov. In this, the eighth edition, Mr Keith Lyle has given it yet another character. It is still no easy reading, but the reader is rewarded with a new outlook on the aetiology of squint in terms of developmental anomaly. Mr Lyle places orthoptics in their right position— invaluable in diagnosis, less valuable in treatment. He urges early operation so that under ideal conditions the squint is corrected before the age at which orthoptics can be used, and makes it clear that long courses of orthoptics divorced from hospital practice—or even associated with it—are a time consuming anachronism. No ophthalmic surgeon can fail to benefit from reading this book.

Hämolyse und Hämolytische Krankheiten

CONRAD MAIER, Oberarzt der med. I. klinischen, Universitäts poliklinik, Zürich Berne Huber 1950 Pp 316 Sw fr 21 80

THIS volume begins with a chemical and physiological description of the red blood cell and its contents.

Figures are given to show that some haemolysis proceeds all the time. Normal serum contains 1-10 mg of haemoglobin per 100 ml. and in some anemias not usually classed as haemolytic this figure may be increased. In pernicious anemia for instance, figures up to 45 mg are recorded and such patients are thought to respond relatively poorly to specific treatment. Dr Maier still devotes much space to Barkan's "easily split off iron" though the modern view is that this is an artefact. Full details are given of the various tests applied to the study of red cells. Mechanical fragility gets no fewer than 10 pages and lysolecithin resistance 6. A brief but notably complete section on immune bodies that cause haemolysis is included and a neat figure makes clear the action of incomplete antibodies.

Rather more than half the book is given over to the physiological matters. Then follows an excellent classification of haemolytic diseases, including some syndromes

of usually recognised in this country as separate entities. The discussion of the diseases listed makes up the rest of the book and it is much less complete than the list itself.

The space given to the various diseases seems to depend on the author's interest rather than on their relative clinical importance. For instance *Marchiafava's nocturnal hæmoglobinuria* has 10 pages, and *hämolytische Anämie Typus mit Bilirubin*, whereas all the conditions due to *Rh* incompatibility are dismissed in 2 pages and the discussion of a difficult subject of acquired hemolytic anemias is similarly sketchy. There is a good bibliography with proper reference to American and British work up to 1950.

Within its limits this is a sound and succinct discussion of the subject. The physiology and biochemistry is longer than the clinical section.

Bone and Joint Radiology

E. MARKOVITS, M.D. head of radiologic department
Elizabeth Hospital Budapest New York and London
Macmillan 1949 Pp 446 57

Dr Markovits when chief of the principal radiological department in Budapest in happier days produced two successful synopses of diagnostic radiology. Descriptive films for radiological appearances are very limited and certainly in English this branch of medicine cannot be adequately dealt with by the synopsis method. This volume is a cross between a synopsis and a textbook, and covers the whole field of bone and joint pathology in considerable detail. The presentation in tabular form is very well done. For each disease there is a brief description of the pathology. This is followed by a radiological description which is in a set pattern for all diseases. The major sub-headings describe changes in the form, the outline and the structure of the bone. Characteristics peculiar to the localisation in a flat or long bone or in the skull are then dealt with in detail. At the end of each section there are numerous differential diagnostic tables and classifications which would be very helpful to the student. The book is liberally illustrated by line drawings and radiographs, and some of the illustrations are not quite up to the standard of the text. The English is excellent, and there is no doubt but that the author has succeeded in presenting clearly and simply a vast amount of knowledge. The book is very expensive, but well worth the money.

Medical Entomology

(2nd ed.) ROBERT MATHESON Cornell University New York Constable London Constable 1950 Pp 612 5s.

Professor Matheson's textbook first appeared in 1932. A group of insects is allotted one or more chapters, and the relation of the group to human disease is discussed and often summarised in tables. The greater part of the detailed information being concentrated in these tables, the author is left free to write a readable text.

The American origin of the book has influenced the amount of space allotted to different groups. ticks are handsomely treated, and the British reader may think the treatment of fleas and mites over-generous compared with the very short chapter on their blood-sucking allies. Professor Matheson is perhaps a little inclined to give solemn warnings about making clear errors, which are necessary. His typical about the efficiency of some destruction as a means of controlling insects. But does not do much an example of the actual use of the method. There is a suggestion that a destruction of "does not seem worth while as domestic animals may also serve as reservoirs" is inadequate to cause which game destruction has been a preliminary to the eradication of domestic animals. In the same way his list of the drugs used in various types of insecticide is a mere list of names. The author's experience. His warning "all the more reason for making use of with care" and has been supported by giving them in a chapter for can.

As a guide to the insect of medical importance this is a good book for both doctors and entomologists. It is a good book for the insect of the entomologist in the field of his own interests.

A Pattern for Hospital Care

ELI GINZBERG PH.D. director of the New York State Hospital Study New York Columbia University Press London Oxford University Press 1949 Pp 368 36s

Professor Ginzberg of the Graduate School of Business of Columbia University with a staff of social scientists and statisticians, has made a survey of hospital care and finances in New York State. His report covers acute general hospital care care for patients with tuberculosis, mental illness and other long term illnesses and care for inpatients and outpatients. The earlier detailed part of the book is heavy going for the English reader who is apt to be unmoved by the problems of New York State, but later the subject matter widens in scope and the chapters on hospital staff appointments supervision of the standard of medical care and principles of internal administration are more easily read. The key factor of administration is the quality of management but Professor Ginzberg points out that in a hospital there are three centres of power none of which is closely integrated with the other. The board of trustees possesses the formal power the doctors are the key professional group but other groups such as the nurses may have secured a high degree of autonomy. Hence the importance of the hospital administrator. Yet

the Board of Trustees seldom makes a specific delegation of authority to the administrator and when it does often fails to support him should he encounter difficulties in dealing with the doctors or nurses. On the other hand the board frequently interferes with the administrator by interjecting itself in his work.

Professor Ginzberg therefore urges that the salary scale of hospital administrators should be raised so as to interest a superior type of person in this career. He suggests that the position might be similar to that of the president of an American university.

Atlas der Haut- und Geschlechtskrankheiten

Prof W. FRIEDRICH late director of the University skin clinic Berlin Prof W. SCHENCKEL director of the university skin and VD clinics Heidelberg Stuttgart Thieme 1949 Pp 266 DM 60

This comprehensive atlas of skin and venereal diseases contains well over 400 illustrations, chosen with skill. All the more common diseases are represented by a series of pictures showing their varieties, rare and very rare diseases including those of the nails are shown in at least one or two pictures. There are a few omissions, such as erythrasma, poikiloderma, and Paget's disease of the nipple. Over 300 of the illustrations are beautifully reproduced from colour photographs. Those of the diseases of the mouth are particularly impressive. Dermatologists and venereologists will find the book valuable for teaching purposes, and general practitioners will welcome it as a work of reference.

Compulsion and Doubt

Vols I and II. WILHELM STEKEL, M.D. Translator
FRANZ GUTHRIE, M.D. London Peter Nevill 1950
Pp 645 36s

This work displays the exceptionally wide range of Stekel's experience, the intuitive approach, the penetration, the impatient energetic therapy and the egotism which were responsible for his fame and his isolation. No one except Janet, has devoted so much attention to obsessional disorder, and the case-histories which make up a large part of these two volumes afford a vivid picture of its symptoms and psychopathology. Of the treatment they give a less satisfying account, doubtless because Stekel was a therapist who moulded data and methods to fit his artistic idiosyncrasy. This attitude, which appear here, sometimes as obiter dicta, sometimes as emphatic generalisations, thus there is frequent reference to the 'poison-complex,' which is finally said to be demonstrable in the psychic structure of almost every case of compulsive disorder. The arrangement of the chapters seems haphazard, the translator provides a corrective for this, however, in his preface which resumes Stekel's views systematically. Though

the book is unsatisfying to the critical reader, it is a storehouse of clinical material, and the outcome of much psychotherapeutic practice

The Liver

Porta Malorum (The Gateway to Disease) KASPER BLOND, M.D., late first assistant, Rothschild Hospital, Vienna, DAVID HALER, M.B., hon consulting pathologist, Westminster Hospital (All Saints Urological Centre) Bristol John Wright 1950 Pp 263 25s

THE thesis of these authors is that "all abdominal disorders originate from liver damage"—that is, from portal hypertension and the impairment of the detoxicatory function of the liver. We are asked to believe that such diverse conditions as "ulcers of the intestinal tract in stomach, duodenum, jejunum, appendix or gall-bladder are caused by one disorder only—i.e. acute or chronic intoxication of the liver." In case one should feel that the hypothesis is too narrow the authors inform us that "the portal blood may even enter the thyroid plexus through anastomoses with the oesophageal vein, and possibly result in a toxic goitre." A considerable amount of somewhat startling factual information is presented in support of these views, but little real experimental evidence. The book can be warmly recommended to those who enjoy finding the weak points in a novel argument.

Diseases of the Foot

EMIL D'W HAUSER, M.S., M.D., associate professor of bone and joint surgery, Northwestern University, Chicago Philadelphia and London W B Saunders 1950 Pp 415 35s

THERE are now a number of orthopaedic textbooks dealing with diseases of the foot, notably those of Lake in this country and Lewin in America. Dr Hauser makes a valuable addition to these, for though his volume adds little that is new it is thorough and systematic, and written with a personal flavour as well as with authority. Some of the author's preferences in treatment are widely shared (e.g., strapping in the treatment of club-foot), others are more controversial, for instance his view that there is some relation between mycosis of the feet and thromboangitis obliterans. It is pleasant to find operative treatment firmly kept in second place. The clinical photographs and the reproductions of X-ray films are very good.

Über die Petrositis (Vienna Maudrich 1950 Pp 99 D.M. 9).—This is a small monograph in which Prof Otto Mayer describes a group of cases and discusses them from a clinical and surgical point of view. The approach is that of the otological surgeon, but the subject is one that interests the neurological physician and surgeon as well. The work is largely descriptive.

Amoebiasis (2nd ed. Cairo Fuad I University Press 1949 Pp 44).—Dr G. P. B. Sobhy deals chiefly with intestinal amoebiasis, though he mentions the important metastatic lesions, such as amoebic infection of the liver. He discusses at some length the clinical manifestations, diagnosis, and treatment, and deals more slightly with the propagation, prophylaxis, and pathology of the disease. Sobhy Bey has had great experience and his views are entitled to respect, nevertheless, in the absence of the data on which they are based some of his statements are open to question. For example, in discussing pathology he attributes inflammation and leucocytic infiltration to "eruption of the parasites in the submucous coat" whereas other writers suggest that until secondary infection occurs, there is a notable absence of leucocytic infiltration in intestinal amoebic lesions. Again, his account of the life-cycle of the parasites in relation to the action of drugs upon them seems somewhat confused. He suggests, for instance, that in chronic cases cysts can be made to hatch by giving extract of ox bile by mouth, so producing diarrhoea, and that the amoebae can then be attacked with emetine. This view seems to overlook the fact that amoebic cysts arise in the intestine from pre-existing vegetative amoebae, and that amoebae appearing with diarrhoea in a patient previously passing cysts are, in fact, amoebae which have not been able to encyst before being swept from the bowel.

Atlas der Blutkrankheiten (4th ed. Berlin Urban & Schwarzenberg 1949 Pp 266 D.M. 60).—The last edition of this book, by Dr Karl Schleich and Prof Albert Alder, was published in 1941 and is not well known in this country. This edition consists mainly of 139 colour plates, all from paintings and admirably clear—sometimes perhaps deceptively clear. The various kinds of cells have a plate each, and the various diseases are represented by whole fields; it is clearly stated whether they are original fields or arranged ones to show the various cell types. The book is divided into two parts, a first section on blood and a second shorter section on bone marrow. This artificial division unusual in modern textbooks, is possibly a relic from older editions. The work is comprehensive, and we remain doubtful whether much is gained by including, for example, pictures of the blood in neutrophil leucocytosis, or in pernicious anaemia in remission, or of large red cells in liver cirrhosis. But there are some very fine unusual plates as well, among which pride of place goes to that of peripheral blood from a 5-6 week embryo.

This, then, is a standard textbook, well executed and reflecting the views of the Swiss school. But those whose German is poor need not struggle with the text, since there are equally good, if not better, books in English.

Essentials of Obstetrical and Gynaecological Pathology (2nd ed. London Henry Kimpton 1949 Pp 350 60s).—This volume, by Dr R. L. Faulkner and Dr Marion Douglass, of the Western Reserve Medical School, will inevitably be compared with Novak's classical textbook. Avowedly aimed at a lower level of the hierarchy of the specialist it gives no references and does not discuss academic points at any length, but it bears the imprint of Novak's school. The short opening chapters on The Surgical Specimen and on Elementary Histology will help the house officer, and the comparative brevity of accounts of rarer conditions will give him a proper perspective. If the type is a little hard on the eyes, the subject matter is refreshingly free from serious error or omission, and the illustrations are liberal though many of the photomicrographs lack sharpness of definition. The approach is always clinical, and the book offers plenty of sound instruction to the postgraduate starting on the long climb to a higher degree in gynaecology. In another edition he would probably be grateful for an additional section on the pathology of pregnancy in general, including the toxæmias.

Doctors Courageous (New York Harper 1950 Pp 292 \$3.50).—Dr Edward H. Hume surveys the history of missionary effort by doctors in four directions—in Africa, in India and Pakistan, in the Near and Middle East, and in China. The account, though not based on the first hand experience which helped to make his *Doctors East and Doctors West* so interesting, is nevertheless written by one who is master of the subject and who can hold the reader's attention in what has to be a highly condensed statement. He makes clear how great is the reward that waits on medical work among the natives and how much has been accomplished by patient and steady persistence. Even the Witch doctors are growing hospital minded and have acquired stethoscopes to impress their patients that they too have a part in the new order of things.

The Common Diseases of the Skin (4th ed. Edinburgh Oliver & Boyd 1949 Pp 274 21s).—Dr G. A. Grant Peterkin has ably concluded the revision of this textbook by the late Dr R. Cranston Low. It is of a convenient size and eminently practical even on the subject of starch poultices real working instructions are given. There are plenty of good monochromes, which prove afresh that, for illustrating diseases of the skin, good black and white pictures can be better than colour photographs, which are often inaccurate and therefore misleading. However, some faithful colour plates of the rightly famous Edinburgh moulds are included. The condition which has long been classified as acute seborrhoeic dermatitis is here taken out of the "seborrhoea" group and is given the provisional name of "flexural infected eczema." Dermatitis would have been a better word, for the term "eczema" is now becoming obsolete but it is to be hoped that others will follow this lead, and include under seborrhoea only seborrhoea capitis, dry scaly seborrhoea corporis, and infantile seborrhoea dermatitis.

THE LANCET

LONDON SATURDAY, DEC 30, 1950

Hepatitis

TILL 1939 infective hepatitis (catarrhal jaundice) aroused comparatively little interest, but during the war the disruption of military plans by epidemics among troops led to investigations throughout the world. Fortunately, this interest has persisted, and after many lean years some progress is being made.

The maximum incidence is in the age group 5 to 15 years, but in these young people the disease is usually very mild, and jaundice is rare in children under 5. Infection at this age may be symptomless or may cause mild gastro enteritis, while attendant viruses develop the full blown disease. Occasionally, however, even in the very young the disease may terminate fatally, either with acute yellow atrophy or after protracted subchronic hepatitis and resulting multiple nodular hyperplasia.^{1,2} One of the cases reported by TRAVISMAN et al.² was thought to be due to transfusion with an icterogenic batch of blood plasma. So called homologous serum hepatitis apparently has a lower attack rate in children,³ but undoubtedly the condition does occur. When a group of susceptible children receive injections from an icterogenic pool, the fatality-rate may be high, among 41 cases in a group who received convalescent measles serum there were 8 deaths⁴, and among 7 cases in a similar, more recent, episode there were 1 death.⁵ It was hoped that these rare incidents could be eliminated by the routine irradiation of serum with ultraviolet light.⁶ However, recent reports from the U.S.A. of hepatitis after administration of irradiated plasma⁶ confirm warnings by McCALLUM⁷ and NEEFE⁸ that this technical procedure needs care. Moreover, the original experiments showing inactivation by ultraviolet light were limited out on only two or three strains of virus. Observations by COCKBURN and his colleagues⁹ on the results of inoculating the gamma globulin fraction of an icterogenic plasma pool confirm the belief that this fraction is relatively non icterogenic. Among 10 recipients of plasma there were 7 cases of jaundice with 3 deaths, but among 58 recipients of gamma globulin there was only 1 case, which was mild. Whether the fractionation procedure involved in making gamma-globulin inactivates the icterogenic agent, or merely masks it by concentrating antibody excess of virus, is unknown. Since 1945 epidemics of infective hepatitis have been uncommon except in the U.S. arm of occupation in Germany, where the

civilian population is little affected.⁹ The reason for this is still obscure, but there seems to be a suggestion that a considerable proportion of these cases are inoculation hepatitis of one kind or another. A further limited source of hazard is infection from handling human sera either in the clinical laboratory or the blood-bank.¹⁰

In 1945 STOKES and NEEFE¹¹ reported that gamma-globulin prepared from ordinary adult serum was, as in measles, a useful prophylactic against infective hepatitis in closed or semi closed communities. This was later confirmed by HAVE S and PAUL.¹² But, once the disease develops, the outcome depends mainly on the patient's own recuperative powers. Most adult patients make a good recovery with no residual damage, but, as we have remarked, acute yellow atrophy occasionally develops in children, and in some adults the acute attack is followed by subchronic or chronic hepatitis and death. Because 'Aureomycin' acts on some viruses, its effect on infective hepatitis was studied in the U.S.A. It was found to have little, if any, influence on the duration or severity of the acute symptoms,¹³ but when given to patients with acute hepatic coma or chronic liver disease it seemed beneficial.¹⁴ Aureomycin has also prevented or delayed the onset of hepatic necrosis in rats on a necrogenic yeast diet. This has led GYORGY and his associates¹⁵ to suggest that aureomycin has no specific action on the virus but inactivates the intestinal organisms, thus preventing formation of bacterial metabolites and giving the parenchymal cells a chance to recover from their purely virus lesion.

In the epidemiological field prospects also look brighter. For many years it has been realised that for every patient with obvious catarrhal jaundice there were probably several with a less severe illness without jaundice. Even in cases with jaundice there is no specific immunological test to distinguish infective hepatitis from obstructive or other types of jaundice. Attempts to infect laboratory animals have been unsuccessful, and no satisfactory diagnostic changes could be observed in developing chick embryos inoculated with infective material. However, ESSEN and LEMBKE¹⁶ reported from Germany that they had produced anicteric hepatitis in man by inoculation with egg cultures, and now HENLE and his colleagues¹⁷ have obtained multiplication of two strains of infective-hepatitis virus—one from faeces and one from serum—in cultures of rabbit-liver and chick-embryo tissues and in the amniotic sac of developing chick embryos. When both types of culture, representing a dilution of the original material of from 10^{-10} to 10^{-20} , were given orally in man, they caused an illness similar to anicteric hepatitis, usually after an incubation period of 20-35 days. Furthermore, intradermal injection of the infected

ing dose of ultraviolet light, gave a positive skin reaction in nearly 100% of patients convalescent from naturally acquired or induced infective hepatitis¹⁸, normal subjects so far tested have given only about 30% of positives. A similar figure was obtained in cases of homologous serum hepatitis—a finding which supports the hypothesis that there are at least two immunologically distinct hepatitis viruses. The thymol turbidity and flocculation tests may not distinguish between serum hepatitis and infective hepatitis in an individual case, but observations by GREEN¹⁹ support the suggestion of MACLAGAN²⁰ and NEEFE²¹ that these tests are less strongly positive in patients with serum jaundice than in those with infective hepatitis. The growth of the virus of infective hepatitis in tissue-cultures is possibly a first step toward adaptation to small laboratory animals and production of large quantities of high titre material for specific serological tests.

Although MACCALLUM and BAUER²² reported jaundice in subjects inoculated with tissue culture of the virus of homologous serum hepatitis, skin tests with this material gave negative results in a small group convalescent from yellow fever vaccine (serum) jaundice. Thus there is still no means of detecting donors who may be carrying hepatitis virus in their blood.

Atherosclerosis and Cholesterol

MUCH of the recent work on atherosclerosis has been based on the assumption that the cause lies partly in the diet, and special efforts are being made to identify the particular dietary constituents concerned. Cholesterol has been under suspicion ever since ANITSCHKOW showed that arterial lesions could be induced in rabbits by adding that substance to their food. Cholesterol is a usual constituent of arterial lesions, and the hypercholesteræmia of diabetes mellitus, myxœdema, and the nephrotic syndrome is commonly associated with atherosclerosis. Nevertheless it is not easy to believe that even transient hypercholesteræmia is an essential factor in a disease so common as to be discoverable (GEIRINGER²³ says) in everybody over the age of eight. Perhaps too much attention has been paid to cholesterol, and too little to the other blood lipids. In 97 men who developed severe coronary disease before the age of forty, GERTLER, GARN, and LERMAN²⁴ found that, though the blood lipid levels were above those of normal controls, the rise in serum cholesterol was not attended by a commensurate rise in phospholipids. There was thus an increased cholesterol/phospholipid ratio, and the investigators took this to be a factor in atherosclerosis. In support of this idea they cited experiments by LADD, KELLNER, and CORRELL²⁵ in which the detergent 'Tween 80' (polyoxyalkylene sorbitan mono oleate) was administered intravenously to rabbits along with cholesterol. Though the animals developed hypercholesteræmia, greater even than that produced by cholesterol alone, they did not develop atherosclerosis—a finding which LADD and his associates attributed to a concomitant rise in phospholipids induced by the detergent. A similar effect was noted by STERNER²⁶ in giving choline along with cholesterol: here again hypercholesteræmia was produced but little or no atherosclerosis, the choline having accelerated the synthesis of phospholipids in the liver. There is in fact a growing body of opinion that the development of atherosclerosis is due more to an upset of the lipid balance than to an excess of any one lipid in the blood.

Another suggestion relates to the physical state of the plasma lipids. Most of these circulate as colloidal particles which are too small to be seen microscopically, but in the hyperlipæmias of metabolic origin, and in the alimentary lipæmia which follows a fatty meal, larger particles appear which can be seen with the dark ground microscope, and MORETON²⁷ has suggested that these macromolecular aggregates, or chylomicrons as they are called, are damaging agents. He believes that they act upon the vessel walls in the same way as do the non lipid macromolecular substances, such as polyvinyl alcohol and methyl cellulose, with which HUEPER²⁸ induced arterial lesions in rabbits, so in MORETON'S view atherosclerosis is the result of 'a lifetime's ingestion of many fatty meals'. In supporting this, BECKER, MEYER, and NECHELES²⁹ have shown that the chylomicrons tend to persist unduly in the blood of old people: in young subjects the chylomicron count rises quickly after a fatty meal and returns to normal within 5½ hours, but in older subjects it may remain high for 24 hours, and BECKER and his co-workers think that this sustained alimentary chylomicronæmia is a factor in atherosclerosis. Further support for this hypothesis has lately been obtained by POLLAK³⁰ who injected colloidal cholesterol of varying dispersions into the circulation of rabbits and found that coarse suspensions induced arterial lesions more readily than fine ones. It appeared that the large micelles were immediately precipitated on the surface of the arteries and phagocytosed by endothelial cells, so that within thirty seconds of the injections accumulations of them were established in the intima. POLLAK holds that macromicelles of β globulin cholesterol and of α globulin cholesterol are the most likely damaging agents, and he argues that their excess in the circulation of older people may be due to a decrease in serum albumin. From this it might be inferred that atherosclerosis results from an upset of the serum protein equilibrium due to inadequate liver function.

The chylomicron hypothesis is not supported, on the other hand, by an investigation of the blood lipid by the use of the differential ultracentrifuge. With this apparatus, which is capable of exerting forces millions of times that of gravity, molecules in solution are made to undergo sedimentation or flotation according to their densities, and their rates of migration can be recorded in Svedberg units. GOFMAN et al.³¹ have applied this technique to the study of the serum lipids, and in recording their relative flotation (Sf) rates found that they fell into the following

classes (a) those with Sf rates greater than 75, which include the chylomicrons and the fatty molecules of alimentary lipæmia, (b) those with Sf values 30-70, which constitute the major fraction of alimentary lipæmia, (c) those with values Sf 10-20, whose molecular weight is in the neighbourhood of 3,000,000, and which contain about 30% of cholesterol (it is this group which appears to be specifically related to atherosclerosis), and finally (d) those with values Sf 3-8, which are the molecules containing cholesterol, phospholipid, and protein—loosely referred to as the B₁ lipoproteins. A clue to the relation of these different classes of molecules to atherosclerosis is obtained from a study of the blood lipids in rabbits receiving cholesterol. In the rabbit there are molecules of an Sf 10-30 class which usually, but not always, increase after long-continued cholesterol feeding. GOFMAN and his colleagues observed that it was only in cases where these were increased that severe atherosclerosis developed, and they therefore concluded that these molecules were the damaging agents. Proceeding then on the assumption that the Sf 10-20 molecules in man were homologous to the Sf 10-30 in the rabbit, they examined the concentrations of the former in various human diseases in which atherosclerosis is prevalent, including coronary insufficiency, diabetes mellitus, the nephrotic syndrome, hypothyroidism, and hypertension, and in all of these found significant increases. They concluded therefore that the Sf 10-20 molecules—which, be it noted, do not include those of alimentary lipæmia—were the particular ones concerned in the development of atherosclerosis. They noted, however, that the Sf 10-20 concentration in man could be reduced by restricting the intake of fatty foods.

From this tangle of information it might be concluded that diet is the all important factor in atherosclerosis, but there are also facts that call for a modification of this view. Atherosclerosis occurs spontaneously in chickens, and HORLICK, KATZ, and STAMLER³² found that it still occurred when most of the fats and cholesterol were removed from the bird's diet. Apparently therefore the endogenous lipids in the chicken suffice to provide for the atherosclerotic process, and probably the same holds for man, which brings us to where we were at the beginning of this review. But it should be noted that HORLICK and his associates found that in the chickens on the low fat diet the lesions were on the whole less severe, so though exogenous fat may not be a necessary factor in the development of atherosclerosis, it is probably a contributory one. Indeed, by feeding chicks on a high cholesterol diet STAMLER and KATZ³³ induced hypercholesteræmia, hepatic lipidoses, and a high incidence of atherosclerosis of the aorta.

On all these counts therefore, it might be inferred that the severity of atherosclerosis could be reduced by dietary treatment, or by the administration of hypotrophic drugs, and such measures have been widely tried. Though in chicks choline and inositol did not prevent spontaneous atherosclerosis or atherosclerosis induced by cholesterol feeding or stilbestrol,³⁴ MORRISON and GONZALES³⁵ have

reported benefit from the administration of choline to patients with coronary disease. On the other hand GERTLER, GARN, and WHITE,³⁶ noting that both in their coronary disease cases and their controls the serum cholesterol levels were "startlingly" independent of the amounts of cholesterol ingested, conclude that "there is no advantage to be gained from imposing a low cholesterol diet on patients with coronary-artery disease." Moreover any hopes of decisively changing the outlook for such people can be based only on the assumption that it is the fatty changes themselves that are directly responsible for the fatal consequences in atherosclerosis, and this is doubtful. In coronary atherosclerosis it is not the fatty change which hardens and constricts the vessels, but the fibrous thickenings, and the nature of these thickenings is still in doubt. They have long been regarded as reactive overgrowths of the intima, excited by the presence of fats, but in resurrecting the thrombosis hypothesis of ROKITANSKY, DUGUID³⁷ has suggested that in reality they are organised mural thrombi. If this is true, the fatty changes can play only a limited part in the process. They may promote the thrombosis, and to eliminate them might reduce the thrombotic tendency, but once thrombosis has begun, the size of the thrombus and the extent to which it interferes with the circulation must depend on factors which govern fibrin formation—and this is a field still incompletely explored. Even if the thrombosis hypothesis is wrong, however, it has still to be remembered that it is not so much the fatty deposits as the fibrous thickenings that interfere with the circulation, and these two changes are not so constant in their relationship as to indicate that they are necessarily interdependent. One sometimes sees coronary thickenings, amounting almost to total occlusion, with little or no fat in them, and it is hard to see how the ingestion of fats could be more than remotely culpable.

Apologia of an Allergist

Dr JOHN FREEMAN, with his friend the late LEONARD NOON, took part in the earliest experimental investigations of hay fever, in 1908, and the way was thus opened to him for those studies of "toxic idiosyncrasies" which have occupied the whole of his working career and are now collected in an imposing but most human and attractive record³⁸. At that time little of value had been published on hay-fever directly, since BLACKLEY's monograph in 1873, which had recognised the condition as due to individual sensitiveness to grass pollen in the air. States of specific sensitiveness, resulting from infections or artificial injections, had indeed been described in the interim, and presented analogies whose significance FREEMAN may be rather too ready to discount. RICHTER had described in 1902, and named "anaphylaxis," a condition of acquired specific sensitiveness in dogs, following an earlier injection, and THEOBALD SMITH had initiated a much wider study of this phenomenon by his recognition of it in guinea pigs in 1904. In 1904 also, von PIRQUET, studying such conditions as "serum sickness" and the accelerated but abortive reaction of the immune subject

³⁸ Hay Fever. A Key to the Allergic Disorders. By JOHN FREEMAN. P. M. London. Heinemann Medical Books 1950. Pp 321 42s

to vaccination, had coined the word "allergy" to describe all conditions of "altered reactions consequent on an infection, or on treatment by some foreign substance", he obviously, therefore, intended the term to cover immunity in all its manifestations, as well as, or paradoxically including, those in which the response indicated an acquired sensitiveness. To FREEMAN and NOON, however, hay-fever seemed in 1908 to present the opportunity of exploring a phenomenon which had hardly, if at all, been touched by experiment, and the enterprise was made additionally attractive by the prospect of finding means of relief, or better of prophylactic treatment, for an often disabling affliction.

From that beginning FREEMAN, after NOON's early death, found himself following the clues of obvious analogy, which led him to a wider study of specific sensitiveness to the now familiar range of provocative substances (food constituents, epidermal dusts, moulds, drugs, &c) and of the varieties of reaction produced by contacts with them, according to the organ or tissue affected—urticaria, rhinorrhœa, asthma, and the rest. And following, as he gratefully acknowledges, the example of his teacher SIR ALMROTH WRIGHT, that connoisseur of neologisms, FREEMAN proposed to name these conditions "toxic idiopathies", the provocative substances were to be "idiotoxins" and the substance in the serum, capable of transmitting the idiopathy to the skin or mucous membrane of a normal subject, an "idioceptor". A purified extract used for diagnosis of an idiopathy was a "pathophane". The nomenclature thus proposed was rational enough, and sufficiently free from theoretical implications, but it did not achieve the general currency which it deserved. "Toxic idiopathy" was, after all, rather a mouthful, and von PIRQUET's "allergy" was available to replace it, though only by a drastic restriction of its original meaning, the derivatives "allergic," "allergen," and "allergical antibody" were ready to hand to complete the range of synonyms. And though "allergy" and "allergic" have suffered a popular debasement in the allusive slang of the music hall and the cocktail party, they have obtained such a hold in medical usage also that FREEMAN feels bound to employ them, as on the title page, though not regularly and consistently.

Dr FREEMAN's book is a very personal document, and it has a very practical character. Every chapter contains records of experiments made by the author, and abundant gleanings from the rich harvest of a lifetime's clinical experience in this special field. The conditions studied being, in the manner of their occurrence and manifestation, peculiar to the human species, there is of necessity a specially intimate relation between experiment and clinical observation in dealing with them. Hay fever itself, the first of such conditions to be studied in detail, and a central point of interest for the author ever since, stands as the type for the whole group. Though the "allergic," or "idiopathic," factor is emphasised, there are full and enlightening chapters on the influence of trauma in localising the reactions, and on emotions, moods, and tensions in precipitating attacks, or even in rendering manifest and active a condition which was presumably already present in a dormant form. It must be admitted that no

satisfactory explanation of such a connection is offered by FREEMAN—or, for that matter, by any body else. He strongly contests a tendency to explain such conditions as simply neurotic in origin, but the nature of the link between the admitted neurotic factor and the biochemical phenomenon of the allergic sensitiveness seems to be left in obscurity: one would like to have some more evidence about allergic reactions on denervated or decentralised areas. Perhaps, too, he might have given less emphasis to the points of contrast, and have found more of interest in the points of similarity, between the fundamental mechanism of anaphylaxis, as produced experimentally in certain animal species and the idiopathies which occur, apparently spontaneously, in man. For example, the reasons which lead him to argue that the "idioceptor" is not an antibody of any known kind are just those which led the earlier workers on anaphylaxis in the guinea-pig to conclude that its "anaphylactic antibody" was something quite special, yet probably nobody now seriously doubts that it is after all a precipitin, predominantly fixed to the sensitive cells. Similarly, FREEMAN describes the serum of the prophylactically treated patient as having "a newly acquired characteristic," somehow masking the sensitising capacity of the blood (idioceptor), which is nevertheless still there. The relation between immunity and anaphylaxis, as now generally accepted, might, by analogy, afford a simpler interpretation. And how does he reconcile the suggestion of a completely spontaneous origin of sensitiveness to egg protein, for example, with the almost complete absence of ambrosia fever in this country and its prevalence in the U.S.A., where ambrosia is so common a weed?

In general, Dr FREEMAN's book provides a feast of information, compounded of observations, experiments, and wise and cautious commentary. Essentially it is the scientific autobiography, though not a chronologically consecutive one, of a genuine pioneer, and it has the individual quality that enables an author's friends to fancy that they hear his voice as they read.

Public-health Salaries

New minimum salary scales for doctors in the public health service were awarded last week by the Industrial Court. The scale for medical officers of health is as follows:

Population up to	Initial	Salary (£)	Annual increment
75 000	1450-1650	50 x 4	
100 000	1550-1850	50 x 5	
150 000	1750-2050	50 x 5	
250 000	1950-2250	100 x 5	50 x 1
400 000	2000-2500	100 x 2	50 x 1
600 000	2300-2700	100 x 3	

Where the population exceeds 600 000 the minimum scale will be followed with annual increments at discretion.

Senior medical officers are to receive a minimum of £1250, rising by annual increments of £50 to £1650, and assistant medical officers or medical officers in departments £850, rising by annual increments of £50 to £1150. Scales for deputy medical officers, divisional or area medical officers, and officers holding mixed appointments are to be determined by joint negotiation and agreement between the parties. The new scale are to operate from Oct 1 last and they will at least improve the position of most of the more senior members of the public health service. Unfortunately they do nothing to attract able men into the junior ranks, and little to give the service the prestige it needs.

Annotations

ALARMING NAMES FOR HOSPITALS

SOME words have such strong associations that they cannot be used neutrally. For many people the word "cancer" is identified with painful death, and the fact that this hopeless attitude is wrong does not mean that it can be ignored. As doctors we know that cancer is a disease like other diseases, and that many of its early stages are both painless and curable. We know these things because we have been taught pathology, have seen patients of treatment, and have examined statistics. Lay people have not had these advantages. They do not know that we can offer no certain cure for every case of malignant disease, and some of them have had to watch a painful death much more closely and painfully than most doctors. "Incurable" is another alarming word, suggesting lingering misery.

It is more than unfortunate, as has been pointed out from time to time,¹ that such words have found their way into the names of hospitals. Hospitals for "incurables," for "consumption," for "the dying" and above all for "cancer," give patients and their relatives a great deal of unnecessary pain and anxiety. One of our correspondents cited the case of a woman whose first intimation that her husband had malignant disease came through a telegram: "Bed available at the Cancer Hospital." This kind of shock can be extremely disturbing. Even those who know they are tuberculous, or dying, or that their disease is incurable, must feel some added load at the heart when they enter hospitals with such doom-laden names, for their friends the name underlines the tragedy. To talk of consideration for the patient and the value of the psychological approach, and so on, and yet to inflict such useless pangs, implies a failure to think straight—or else to take enough thought. No doubt there are difficulties financial or other, in the way of changing hospital names, but if they should be examined patiently and minutely, they can be overcome. It may well be inconvenient to make changes; it cannot be impossible. Doctors at any rate will be unwilling to put convenience before the ease of mind of patients, and it lies in the hands of the medical staffs of these hospitals to convince their less informed, less sensitive, lay colleagues that for good or evil much can be done in a name.

HYPOGLYCAEMIA

In their milder degrees the symptoms of hypoglycaemia are too vague and varied to be picked out from among the many similar symptoms which form the stock-in-trade of words into outpatient departments. The first changes are in higher cerebral function and in the ability to reason competently is lost and the subject may be unusually morose or garrulous, though he is often able to continue a routine task, such as driving a car. If the hypoglycaemia is a little more severe there are associated symptoms and signs of adrenaline release—particularly pallor, sweating, dilatation of the pupils, tremor, and feelings of fear, coldness, and hunger. If the attack progresses there may be a phase of neuro-muscular overactivity before the onset of disorientation and, eventually, coma—which is sometimes associated with convulsions. The dominance of neurological disturbances reflects the unique position of glucose as food to the nervous system: the effects of glucose deficiency are practically identical with those of anoxia or disturbed enzyme function, for with each of these metabolism is curtailed.

Hypoglycaemia may be due to deficient glucose absorption (for example, in myxoedema and long

continued starvation), to excessive urinary loss, as in severe renal glycosuria, or to deficient glycogenolysis, which may occur in advanced cirrhosis and in von Gierke's disease. Lastly, there may be relative or absolute insulin excess. Relative excess is a feature of Simmonds's cachexia and Addison's disease, whereas true excess may be produced by islet cell adenoma or carcinoma of the pancreas, or simply by functional overactivity of a histologically normal pancreas. To functional overactivity has been ascribed the post-gastrectomy hypoglycaemic syndrome, otherwise such overactivity is found mainly in nervous patients, whose vague hypoglycaemic symptoms may easily be dismissed as not due to any organic cause. In practice the differential diagnosis of causes of hypoglycaemia is usually difficult only when considering islet cell adenomas and functional hyperinsulinism. Typically the patient with an islet cell adenoma has progressive symptoms, whereas with functional hyperinsulinism the symptoms are more capricious. Functional hypoglycaemia usually comes on some 4 hours after a carbohydrate meal, which presumably provokes excessive insulin secretion, the hypoglycaemia of an islet cell tumour, on the other hand, is more marked as the interval since eating increases. Functional hypoglycaemia responds to frequent feeding on a high protein diet,¹ whereas with islet cell adenoma this treatment is not long effective.² If the fasting blood sugar is persistently 50 mg per 100 ml or less, the cause is more likely to be tumour than functional, and it is worth noting that the fasting level gives more reliable information than the glucose tolerance test.³

With regard to treatment, much depends on accurate diagnosis, for surgery can offer much only in cases of adenoma. Whipple⁴ will operate only where the following three criteria are fulfilled: (1) attacks come on in the fasting state, (2) during an attack, or after a long fast, the blood sugar is below 50 mg, and (3) the attack responds readily to glucose. With this strict choice he found a tumour in 80% of the patients operated on. Whipple (whose surgical mortality was 12%) recommends that the duodenum be mobilised so that the head of the pancreas can be adequately palpated between fingers and thumb. In these cases the hyperglycaemic action of ether as anaesthetic may be desirable. When the criteria of organic hyperinsulinism are present and yet no adenoma can be found, subtotal pancreatectomy can be expected to produce a cure in 40% of cases and improvement in a further 10%.⁵ not uncommonly the resected pancreatic tissue contains an adenoma which was previously overlooked. After operation temporary diabetes is common, indeed it is a hallmark of success. The pathological classification of islet cell tumours correlates poorly with the clinical classification, for many such tumours are non-functional and others which appear to be invading blood vessels are in fact benign.⁶ The rare true carcinoma of islet tissue may cause rapidly progressive hypoglycaemia and is unique in that the more it metastasises the more the patient may gain in weight, since he increases his food intake to compensate for the excess insulin. Here surgery is almost always unavailing, as a last resort alloxan may be tried, though it has never been shown to produce more than temporary remission⁷ and neoplastic β cells appear to resist its action more than normal β cells. For functional hyperinsulinism which responds insufficiently to diet,

adrenocorticotrophic hormone (A C T H) has been employed for its diabetogenic action, sometimes the improvement has outlasted by some time the period of administration⁸

ANTIBIOTICS IN OPHTHALMOLOGY

The newer antibiotics were discussed by the Royal Society of Medicine's section of ophthalmology on Dec 14. Outlining the place of antibiotics in the treatment of systemic affections, Dr T B Maxwell remarked on the relative specificity of penicillin, streptomycin, 'Aureomycin,' chloramphenicol, and 'Terramycin', and he brought out the advantages sometimes of administering more than one antibiotic.

That the results obtained in systemic affections cannot readily be applied to the eye was emphasised by Prof Arnold Sorsby. He pointed out that ophthalmologists readily adopt the concept of the eye as functionally a double organ with a dioptric apparatus and a receiving mechanism. But pharmacologically, too, the eye is a double organ—the lids, conjunctiva, adnexa, and sclerotic may be grouped with the other systems to which the general rules for administration of antibiotics apply, but in the avascular part of the eye—the cornea and the aqueous and vitreous humour—a lower concentration results from systemic administration of antibiotics. The blood aqueous barrier is responsible for low concentrations in the aqueous and vitreous, and indirectly in the cornea. In using the newer antibiotics the lessons from the use of penicillin have to be borne in mind. Against eye infections systemic administration of penicillin is not particularly effective. Local application seems to offer some promise, but drops are readily washed out, and ointments are only a little better. The most effective method of application is undoubtedly subconjunctival injection, which causes a depot of the agent to persist around the eye for some hours. If adrenaline or other vasoconstrictor is added to the subconjunctival injection the intra ocular level is both higher and more persistent. With a dose of 1 million units of penicillin subconjunctivally, the concentration in the vitreous is almost as high as that achieved by the introduction of 5000 units directly into the vitreous. These results also apply to streptomycin, and probably also to aureomycin and chloramphenicol, though the behaviour of these last two drugs is very different from that of penicillin and streptomycin. For the present it seems that with these agents subconjunctival injection is still the method of choice, unlike penicillin and streptomycin, however, aureomycin, chloramphenicol, and terramycin are relatively insoluble, and existing preparations are fairly irritating. Professor Sorsby and Dr N B Bailey have found that in the proteolytic type of corneal ulcer due to gram negative bacilli good results are obtained by subconjunctival injection of streptomycin (0.5 g in 1 ml of solvent containing 10 minims of water and 5 minims of adrenaline), and this is a valuable addition to the control of corneal infections. Streptomycin systemically, said Professor Sorsby, has a definite place in the treatment of tuberculous keratitis and phlyctenular ophthalmia, in phlyctenular ophthalmia it both cuts short an acute attack and reduces the risk of recurrence. Sorsby and Bailey have found streptomycin of little use in iridocyclitis and in Eales's disease.

The effect of aureomycin on trachoma, superficial punctate keratitis, dendritic ulcer, and disciform keratitis was discussed by Mr Derek Ainslie. Systemic administration has not proved particularly valuable. Trachoma has responded to aureomycin locally, while two cases of disciform keratitis did well on subconjunctival injection of 5 mg. Dr Ruby Joseph likewise reported a good response, in a case of disciform keratitis,

from two injections of 10 mg of aureomycin. Nevertheless, the irritative reactions are an almost definite contra indication except with pure aureomycin, which she was able to use in her most recent case of epidemic keratoconjunctivitis.

A STUDENT TUBERCULOSIS CENTRE

STUDENTS are more liable to contract tuberculosis than other young people. It has been estimated that 0.2% of those in universities, technical colleges, and training colleges, and 0.9% of those studying medicine, are obliged to interrupt their studies for a term or more because of the disease, and this leaves out of account those who are able to carry on despite a tuberculous infection.

On another page Prof F R G Heaf, Mr C R Morris, and Sir Alan Rook announce the launching of the British Student Tuberculosis Fund. A committee to administer the fund has been set up, on which are represented student and teacher organisations, and bodies interested in the health of students and in tuberculosis. The aims are clear cut—to give help of every kind to British or other students with tuberculosis, and to set up a tuberculosis centre where students, after a period of sanatorium treatment, may complete their recovery and also carry on with their studies. Centres of this kind have been maintained for some time in France, and the committee have already made a study of them. The incidence of tuberculosis among French students (numbering some 130,000) is 1.4%. The service helps them all, and throughout treatment they are encouraged—subject to the recommendations of their physician—to go on with their studies. They stay, on average, 10 months in a sanatorium and 10 months in the reablement (or "post cure") centre, and 60% of them are able to sit for their examinations.

The committee define the word "student" as "a senior or student member of a university or other institute of higher education"—a definition which (whether intentionally or not) seems to open the gates, not only to undergraduates, students, and teachers, but to most postgraduates, regardless of whether they still have any connection with their universities. The numbers thought to be affected, however, amount only to 250, and it is proposed that the centre should begin with 100 beds. The cost of buying, converting, and equipping such a centre is put at £50,000, and since this is an enterprise on behalf of students, and largely initiated by students, the proposals for raising the money are pleasantly vigorous and racy. The national appeal committee have set for every university, college, medical school and teaching hospital in the country a target of 2s 6d per student—not necessarily to be raised by donations (though many may wish to give this amount or more) but rather by such things as athletic events, rag days, concerts, plays, dances, socials, carol singing, jumble sales, stamp sales, or in any other ways that ingenuity suggests. Every interested centre of education is being asked to set up a strong appeals committee, who will open their campaign by writing to every university or college society (even chess clubs will be swept into the arena) to know what activity each can arrange to raise funds for the appeal. Illustrated articles will appear in student journals, the local press will be asked to help, teachers will be invited to make announcements at the beginning or end of lectures, posters will be available, college clubs will levy, on behalf of the fund, "entertainment tax" at their functions, and the national appeal committee in London, will sponsor lecturers to be invited down, provide slides to appear in cinemas and give any other help it can to the local committees. University College, London, is leading the way with a plan designed to bring in several thousand pounds.

DERMATOLOGICAL ASPECTS OF
UNEMPLOYMENT AND RESETTLEMENT

MARK HEWITT

M.B. Lond., M.R.C.P.

SENIOR MEDICAL ADVISER, MINISTRY OF LABOUR AND NATIONAL
SERVICE, NORTH WEST REGION, CLINICAL ASSISTANT,
MANCHESTER AND Salford HOSPITAL FOR
DISEASES OF THE SKIN

OCCUPATIONAL resettlement after prolonged incapacity through skin disease has received little attention. Experience of such resettlement has been confined to the services (Bolam 1945), where patients were under military discipline. Restoration of function for return to duty was the prime concern, and the willing and fit man was easily fitted into a suitable job at the end of his course, while the unwilling, or completely unfit, were released into the civilian community. All these circumstances contrast strongly with those encountered in civilian practice.

The Disabled Persons (Employment) Act, 1944, was intended to help disabled people whose physical or mental handicaps were substantial and who might have to change their employment. From my experience of the work in employment exchanges in the north west of England I have tried to assess what the Act has done for people disabled by skin diseases. I shall also comment on the extent of the problem, on the resettlement results in a group of these patients, and finally on the contributory causes of unemployment in a separate group of 50 registered disabled unemployed persons suffering from skin disease.

Under the Act the disablement resettlement officer (D.R.O.) maintains a register of employed and unemployed disabled persons, and his main concern is to resettle the unemployed satisfactorily in suitable occupations. Besides facilities for placing them in jobs, he also has at his disposal valuable training schemes for skilled work. For the more severely disabled, there are sheltered employment and ancillary home working schemes. Industrial rehabilitation in the early stages of recovery is provided at 13 centres recently established throughout the country (Ministry of Labour and National Service 1948), where, by means of expert vocational guidance, the disabled are helped to adapt themselves to work most suited to their disability and remaining abilities.

THE DERMATOLOGICALLY DISABLED

Dermatological cases present industrial medical officers with a major medical problem and personnel managers with a difficult management and resettlement problem (Hedder Smith 1947, Crosthwaite 1946, Schwartz et al 1947). There seem to be no accurate figures for morbidity due to skin disease in the civilian population, but in the Army skin diseases are one of the main causes of admission to medical units, ranging from around 15% of total admissions in temperate climates to something approaching 20% in tropical and subtropical zones (Army Medical Statistical Department personal communication).

Paradoxically, of 935,007 registered disabled persons (R.D.P.) over the whole country, only 9512, or about 1%, were registered with skin disabilities, and of these 689 were unemployed (October, 1949). Possible explanations of these low figures are a natural disinclination on the part of these patients to register their disabilities, a well known reluctance on the part of works managers to employ them if the diagnosis is known, a tendency for pre-employment medical examination to prevent their obtaining employment, and a lack of appreciation on the part of their medical advisers of the value of early and satisfactory resettlement as a form of therapy. Alternatively, the figures may portray a satisfactory situation and suggest that no real problem exists.

Table I gives five selected types of disability, showing the total registered disabled persons—the number unemployed and the latter expressed as a percentage of the former—with the purpose of providing some impression of their relative success in obtaining and retaining

TABLE II

Regions	Registered disabled persons			Unemployed registered disabled persons		
	Total	With skin disabilities	% of total	Total	With skin disabilities	% of total
London and S.E.	217,690	2506	1.17	11,105	144	1.3
Eastern	43,634	486	1.11	2021	31	1.55
Southern	38,426	410	1.06	2179	33	1.52
South Western	45,142	488	1.08	2962	29	1.04

Gt. Britain	935,007	9512	1.02	65,367	689	1.05

employment. The unemployed are classified in two ways:

- 1 Those capable of ordinary employment, as opposed to those likely only to obtain sheltered employment
- 2 Those unemployed under and over 26 weeks

Similar figures for all disabled are included.

Only 2.6% of those registered with amputations of one arm and one leg are unemployed—a figure which reflects the relative ease of resettling the obviously disabled man. Internal diseases—such as bronchitis and heart disease, which respectively account for 10.9% and 9.4% of the registered disabled unemployed—present a problem second only to that of pneumoconiosis, which in South Wales is responsible for unemployment in nearly a third of those registered as disabled by the disease. In contrast only 5.8% of those registered with pulmonary tuberculosis are unemployed. The percentage of unemployment among those registered as disabled by diseases of the skin and dermatitis (7.2) is about the same as the percentage of unemployment among all registered disabled persons (7).

TABLE I—SELECTED GROUPS OF DISABLED PERSONS, OCTOBER, 1949

Disabilities	Total registered disabled persons	Unemployed			Duration of unemployment	
		No. of disabled persons	% of total registered	Capable of ordinary employment	Requiring sheltered employment	26 weeks and under
Amputation one arm and one leg	14,599	375	2.6	337	38	204
Bronchitis	58,448	627	10.9	552	75	2810
Disease of heart	51,024	529	9.4	457	72	2735

Tuberculosis (respiratory)	47,132	273	5.8	229	44	1651
Total all disabled	935,007	65,367	7	55,619	10,748	32,644

TABLE III—INSURED POPULATION AND NUMBER OF PERSONS WITH REGISTERED SKIN DISABILITIES FOR SELECTED TOWNS AND WHOLE COUNTRY

Selected employment exchanges	Insured population	No of R D P s on register with skin disabilities	% of insured population
St. Helens	51 000	68	0.133
Northwich	18 508	42	2.2
Horden	13 171	11	0.9
Wigan	44 880	55	1.22
Walkden	13 920	16	1.14
Glasgow	560 581	149	0.26
Leeds	287 400	103	0.39
Sheffield	242 390	82	0.34
Cardiff	133 720	42	0.32
Birmingham	609 895	210	0.34
Manchester	501 640	145	0.29
Willesden	89 530	28	0.31
Gt Britain	20 500 000	9512	0.46

The age group distribution of skin disabled unemployed also resembles that of the whole unemployed disabled population, showing the same correlation between age and unemployment. Of the 261 persons with skin disease who were unemployed for more than twenty six weeks 209 were over 41.

DISTRIBUTION OF CASES

Table II shows the division, according to region, of registered disabled persons and those registered with skin disabilities. Apart from the relatively low percentage for Scotland, the skin cases appear to be evenly distributed through the country. Table II also shows the total unemployed disabled persons and those unemployed with skin disabilities. Resettlement seems to be most satisfactory in Scotland and the East and West Ridings of Yorkshire, and least satisfactory in the Midland region.

The figures for the cities shown in table III are well under the national average. Of these, Leeds has a slightly higher percentage than any of the others. These low figures are counteracted by a high incidence in towns where industry is purely chemical—e.g., Northwich.

Coalmining appears to account for the high incidence in Wigan and St. Helens, though the high figure in the latter is probably partly attributable to the glass processing and ancillary industries. The incidence in pure coalmining areas such as Walkden, Lancashire, and Horden, co. Durham, is twice as great as the national average.

A SAMPLE FOLLOW UP

A series of 100 consecutive persons with skin disabilities who applied to become registered disabled persons at exchanges in the North West were medically examined and their progress in resettlement was followed for a year (table IV).

Resettlement was regarded as successful if the man was working at the job six months after he had been

placed in it. The placing performance of the D.R.O. was encouraging, but many of the cases were unemployed for some time before finding work. The success of rehabilitation and resettlement schemes will vary locally and nationally with the labour demand. Analysis of the results of the 100 cases by diagnostic groups was not significant. It was, therefore, felt that a detailed review of a group of unemployed skin cases might be useful.

ASSESSMENT OF CAUSES OF UNEMPLOYMENT

From exchanges in the North West 50 unselected unemployed skin cases (43 men and 7 women) were medically examined, and their occupational, social, and medical history was taken in detail. The method of assessment used is shown in table V.

The figure on the opposite page shows the relative importance of each factor in maintaining the unsatisfactory condition of the patient. It will be seen that the malady itself ranked low in comparison with the dominant position of unsatisfactory work records and social problems.

Length of Unemployment

Unemployment among the disabled in a time of full employment—98.5% of insured men are today working—is itself a disability due to many factors and leads to

TABLE IV—RESULTS OF ONE YEAR FOLLOW UP IN 100 UNEMPLOYED DISABLED SKIN CASES

Satisfactorily resettled	36	Rejected as unsuitable for D P register—no evidence of skin disability. No follow up	9
Found work themselves and satisfactorily resettled	19	Not satisfactorily resettled	1

	65		35

further unemployment (Hewitt 1949). It indicates deep seated medico social difficulty and it is found among inadequate people. The point rating here is based on duration of unemployment up to the time of interview. The shorter the duration of unemployment the more favourable the prognosis.

Previous Work and Unemployment Record

The rating of work records was based on a knowledge of the man's employment record since leaving school. Those most highly rated were men with long spells of unemployment or those with a history of a large number of jobs in a relatively short period interspersed with

TABLE V—METHOD OF ASSESSMENT

Point rating	6	5	4	3	2	1	0
Length of unemployment	37-48 months	25-36 months	13-24 months	7-12 months	13-26 weeks	5-12 weeks	1-4 weeks
Work record	Very bad	Bad	Fair	Fairly good	good	Very good	Excellent
Length of compensation	37-48 months or still in receipt of whole or partial	25-36 months	13-24 months	7-12 months	13-26 weeks	5-12 weeks	1-4 weeks
Severity of skin disability (objective)	6	5	4	3	2	1	0
Degree of mental abnormality	6	5	4	3	2	1	0
Degree of social problem	6	5	4	3	2	1	0
Extent of other physical handicaps	6	5	4	3	2	1	0
Age in years	61+	56-60	51-55	46-50	41-45	36-40	31 and below

periods of unemployment, the lowest rated were those who had remained in the same job for long periods with no unemployment, or those with a few changes of jobs and no intervening unemployment. Allowances were

FACTORS

made for the irregularity of the work of the unskilled labourer and the economic fluctuations which bring unemployment first to him. A man's working career was assessed on his record before the onset of the skin disease, for this new factor was often a heavy handicap which disturbed his former occupational stability. Grossly unsatisfactory work records were the salient feature in this group of cases. To many the onset of the skin trouble seemed to suggest a means of early retirement with a relatively contented state of mind. Others, after a series of attempts to return to work for successively smaller periods, lapsed into a state of complete unemployment. In some the skin condition began on return to work after long spells of unemployment, or (in the case of the women) on returning to work because of economic necessity or war exigency after a long settled period of domesticity. In the majority, however, the skin condition appeared to be the culminating upset in a working life generally unsatisfactory from other causes and seemed indistinguishable from other types of breakdown.

Occupational resettlement depended on the kind of work available in the local industries. The general demand among these men and women was for light and clean work when previously they had only been accustomed to the heaviest and dirtiest work. For example, a woman of 54 of low intelligence who had always worked as a charwoman sought a job free from dust, liquids, oils, chemicals, and fumes. Any job she could be offered was of course unsuitable because it was likely to provoke a recurrence of the skin condition.

Compensation or Industrial Injury Benefit

This was rated according to the length of time for which it had been received. The heaviest rating, 6, was given to those who had received compensation for 37-48 months or to those who were still in receipt of partial or total benefit. Most of this group feared that return to work would result either in their rejection or loss of compensation payment. The longer the compensation and invalidity, the more unhealthy becomes the patient's attitude towards a return to work. Discussions with shop stewards, union secretaries, and solicitors, and the unnecessarily multiplied medical consultations, all tend to accentuate his anxiety about his skin condition and reduce the likelihood of a healthy attitude towards employment.

Degree of Skin Disability

The following types of skin disease were encountered

- (1) Eczema and seborrhœa (47 cases)
 - Seborrhœic dermatitis
 - Unspecified eczema
 - Sycosis
 - Acne vulgaris
 - Acne rosacea

18
24
2
1
1

(2) Other conditions

- Psoriasis
- Chronic leg ulcer
- Lupus erythematosus

1
1
1

The 18 cases of seborrhœic dermatitis had easily recognised lesions in the scalp, retro auricular axillæ folds, pubic region, and interdigital spaces of the feet. The "eczema" lesions were chiefly of the patchy or discoid type and were largely restricted to the extremities. A few had a pompholyx response with vesicles between the fingers. Most of the cases were of the chronic type with thickened lichenified skin, accentuation of the normal skin markings, erythema, desquamation, and fissuring. A few showed palmar discs of hyperkeratosis and fissuring.

Both cases of *acne vulgaris* were in young men; they were slight to moderate in severity, but they were associated with an abnormal degree of self-consciousness. Both these patients had unsatisfactory work-records and domestic social problems. The patient with *acne rosacea* was a young man discharged from the Forces with a severe anxiety neurosis after being a prisoner of-war in Japan.

Of the 2 cases of *seborrhœic sycosis*, 1 was moderately severe with active lesions and marked residual scarring in a man with a bad work and sickness record and a parallel history of miners' nystagmus. In the other case no activity was visible but the man had an atrophic and telangiectatic skin, the result of excessive X-ray treatment. He had an obsessional attitude towards employment; lest his skin condition should be revived by any form of work.

The other 3 patients were

1. An elderly man with slight *psoriasis* on both legs. He had severe myocardial degeneration with early symptoms and signs of congestive failure which he chose to ignore in favour of the visible skin disorder.

2. An inadequate youth with a large *leg ulcer* of uncertain origin which had not responded to hospital treatment (inpatient or outpatient) over three years. He had done little work before or after its onset and had become mired to a state of chronic invalidism.

3. A woman of 26 with a severe disfiguring facial *lupus erythematosus* with gross circumoral scarring. She was four months pregnant and had a child of 7, a lodger, and a large house to look after. She was looking for work because her husband, a drunkard, ill treated her and offered no financial support. Her work record was good but the combination of factors had made her unemployable.

In only 3 patients was the objective appearance of the skin trouble likely to render employment difficult.

The 35 who had previously been certified as suffering from industrial dermatitis all belonged to the seborrhœic eczema group and were indistinguishable from the constitutional type. In 14 of the 35 there were no active skin lesions, and their unemployment was due to other factors, such as the fear of recurrence if any work was undertaken. Such assertions as "The skin trouble will come back if I get a job and sweat," or "I am not taking any risks at all through going back to work" give some idea of this frame of mind. The sickness records of these patients were particularly unsatisfactory, but it was difficult to elicit a true picture. Many of them in the early stages of the condition, after an initial spell off work, had returned to their old employer for a few days or weeks, but recurrences had led to successively longer spells of sickness and served to convince the patient that his skin condition was due to irritants encountered at work—though most of them on their return had been placed in jobs far removed from any primary irritant and in which no possible hazard was present.

Many of the cases had occurred during war time in Government factories and the personnel had been maintained in light jobs with some success until the end of the war. They had then fallen back on compensation and many were still waiting for their claims to be settled. Treatment of these cases by the works medical officer was unsatisfactory.

Mental or Emotional Abnormality

Though most of the skin diagnoses were of the eczema seborrhoea diathesis, no mental characteristics common to all of them were apparent. The majority were of inferior calibre physically and mentally, and the general term constitutional inadequacy was appropriate. Subnormal intelligence was the most usual finding. It was well defined in 12 cases and seemed excellent ground for superimposing emotional abnormalities, of which the commonest variety was a mixture of obsession about the skin condition and in almost hysterical state inhibiting the use of the hands and preventing the patient from doing any work. The reluctance to return to work may have been based on dread of recurrence of the skin condition, but it seemed much more to resemble a hysterical symptom. This view was supported by the general apathy of these patients, their lack of ambition to work and earn a wage, and their obvious dependence on others, including the State, coupled with their unsatisfactory work and sickness records. Those who had had many jobs were sometimes obviously unstable in temperament and often moved from one firm to the other on grounds of industrial misconduct. Persistent anti-social behaviour was noted in 3 patients, one of whom was the child of divorced, drunkard parents, educated at a reformatory school. She had deserted her husband and four young children. The skin disability, though healed at the time of the interview, was her third industrial accident that had been compensated by lump sum settlement within five years.

In the following 3 cases there was a severe anxiety neurosis.

1 A collier with an excellent work record and a large dependent young family. He had what appeared to be a constitutional seborrhoeic dermatitis and, in addition, a moderate degree of hypertension. When seen he was actively discussing his case with solicitors, union officials, &c., and though technically seeking employment and receiving unemployment benefit, he had been advised by his solicitors not to return to work and was greatly upset by his dilemma.

2 An elderly man with eczema on the hands since childhood, who had abandoned an exceedingly good lifelong business three years before on hearing that his only son had been killed in a flying accident. He was in a most pathetic broken-down state with exacerbation of the skin condition and a moderate degree of hypertension.

3 A woman of 32 who had recently married a man of 81 and had as a result been ostracised by both families. She was also pursuing her claim for industrial injury benefit on account of a coincidental outbreak of eczema on her hands.

The aggrieved and aggressive attitude associated with compensation cases was obvious both where the case was still pending and where there was dissatisfaction with the settlement.

Social Problems

According to the Registrar General's classification of social class, 3 belonged to grade III, 1 to grade IV, and 46 to grade V. Because of their disability, the 4 men in grades III and IV were now seeking unskilled work.

Their school records showed that 45 had attended elementary schools but 6 were still in a very low form when they left, 1 had received his whole education in an orphanage and 1 at a special school for the deaf and dumb, and 2 had been educated chiefly at reformatory schools. Only 1 had attended a secondary school, and he had left after three years because of difficult domestic circumstances.

The income of the group consisted of unemployment benefit, extended benefit, or payment from the Assistance Board. In 9 cases compensation, whole or partial, was still being paid, and a number were still living on the remains of their lump sum settlement. As one man said, "My compensation is my wage now." Another

revealed his weekly compensation cheque for £2 8s 11d with some satisfaction. The wives of 5 men were working; many men had adult children supporting them or living with their wives and families in lodgings at the parental home. Of the 7 women, 3 had husbands who were working and the remaining 4 women were housekeeping for parents or siblings who were wage earners. Many were receiving family allowances.

The total family income of one man who was staying at home to do the housework was £8 13s 4d. He had no signs of active skin disease and was keeping two pigs and fifty head of poultry. He was getting compensation and he remarked that if he had a bit of capital and could get his case settled he would like to set up with pigs and poultry.

Other social problems included people who were separated, or divorced. Some of the elderly men had invalid wives. Deaths among near members of the family were another source of trouble, 2 patients had been to prison and 1 was an Army deserter.

The fear of skin disease and dermatitis is prevalent among employers and fellow workers, who are generally ignorant of its real nature, are afraid of infection, and associate it with uncleanness and venereal disease. The self-consciousness of the man or woman who has visible skin lesions constitutes a social disability, which, together with the skin disease itself, produces an ostracism like that experienced by the epileptic and tuberculous. Industrial dermatitis, real or alleged, is more destructive of morale than is generally recognised.

Other Physical Handicaps

Of the 50 patients, 28 had additional disabilities though few were serious. Hypertension (5), dyspepsia (5), bronchitis (3), and deafness (3) were the most common. There was a deaf and dumb youth of 18 and a man with severe myocardial degeneration, but in the remaining 10 the second disability was slight. Of the cases of bronchitis 2 had associated eczematous lesions from childhood and were of the syndrome comprising eczema, asthma, and hay fever. Of the 5 cases of dyspepsia 2 had duodenal ulcers. Most of the group were of poor physique but there was no evidence of malnutrition secondary to poverty.

Age

Increasing age worsened the prospects of resettlement as one man remarked "If you get dermatitis, no employer wants you, especially as you get older." Age in itself is a disability, particularly amongst men who are only capable of unskilled labour, and in this group 26 men were between 41 and 64 years old. Age is one of the most important factors considered by employers when hiring labour and certainly one of the most easily ascertainable. Training for a new skill is seldom practicable in men over 35. Furthermore, the lighter jobs, most desirable for the elderly, are usually done by women.

DISCUSSION

This is an investigation into the failure of people with chronic skin diseases to adapt themselves to their disability, which leads to the interruption of their working life by sick absence and unemployment. It is hoped that the findings will help workers who are trying to prevent this happening. Imperfect mental adaptation to chronic disability plays a great part in long continued sick absence from work and unemployment amongst disabled persons, particularly those with chronic skin disease.

People with skin diseases provide an invaluable opportunity for investigation, because the extent of their physical incapacity can be directly observed. Assessment of incapacity from emotional, mental and social problems is purely subjective and cannot be scientifically accurate but no apology seems necessary for their inclusion in this paper, in view of their paramount importance and

the tendency for them to be omitted in the development of specialities

Fuller consideration of problems other than the purely dermatological ones may enable doctors to help patients before the stage of chronic sickness and unemployment, or resignation to both, is reached

The points raised serve to show the close relation between the disability state, social environment, and occupational record, and that each can only be fully appreciated by consideration of the others. The basic causes of the unemployed state and of prolonged sick absence from work appear to have much in common

Valuable resettlement services are available for skin cases which are not being fully used. The largest group of sufferers are those ostensibly breaking down with industrial dermatitis, and though they present themselves with skin trouble they have many other problems which tend to be lost sight of

I have not tried to compare the factors recognised in this series with those responsible for inability to obtain work among other groups of disabled. But I believe that similar research among these groups would give similar results

SUMMARY

The resettlement of skin cases seeking employment at a late stage of their illness is difficult to secure. A study has been made of 50 unemployed disabled persons suffering from skin disabilities registered at employment exchanges in north west England. Histories were taken, social detail and employment records analysed, and the patients clinically examined. The following main points were elicited

Unemployment amongst these patients is due to more than one factor

Out of 50 patients 46 were unskilled

Out of 50 patients 47 were found to have seborrhoeic eczema

Out of 50 patients 35 had been certified as suffering from industrial dermatitis

The effect of such diagnosis and certification seems usually to have been unfavourable to prognosis

Unemployment in registered disabled persons with skin disease is a symptom calling for full medical social investigation.

I am indebted to the Regional Controller and my colleagues of the Ministry of Labour, North West region, for their helpful operation, to Prof. R. E. Lane for criticism, and to Dr. J. H. Weston Davies for encouragement and advice in the preparation of this paper

In the clinical years too, instruction is passed together with the contributions of independent departments, which differ as much in their philosophy as in their technique. So much of it is given in the hospital wards, where the student finds only people sick enough to be asked. For a sample of the great majority of patients, who are not sick enough to be asked, we must go to the outpatient department, which is commonly organized in such a way that it is hard for the student to learn, or for the patient to find coherent and comprehensive answers. Only by the grace of God, which rarely becomes operative until after the medical degree, is the medical degree and its associated studies, which are not medicine, less than the study of the human body, as the Annual Report of the Medical Research Council, 1949.

PINK DISEASE

LECTURE BY SIR STANTON HICKS

SIR STANTON HICKS, speaking on Dec. 12 at the Ciba Foundation, London, traced the history of the recognition of pink disease, particularly in his native Australia. At one time, he said, this disorder was known by nearly thirty different names, including erythroedema. The title "pink disease" was adopted in 1914 by Swift, of Adelaide. In his later reports Swift emphasised that this is no rare disease—an observation fully confirmed since then.

Cheek, in 1949, found 136 cases in the records of the Adelaide Children's Hospital over a 10 year period—and this despite a policy of treating such cases in their homes to minimise cross infection. Of these 136, 15 died, and half of the deaths were attributed to broncho-pneumonia. Cheek noticed that the areas with heavy incidence of pink disease correlated roughly with those of swayback in sheep. Swayback was known to be associated with cobalt deficiency, and so he turned to the possibility that a mineral trace element deficiency might also give rise to pink disease. With the help of a spectroscopist to determine plasma cations by flame photometry, he studied the sera of 16 cases of pink disease and 16 controls. The plasma sodium levels of the control group were normal, whereas in the cases of pink disease the level was consistently lowered beyond the limits of error of the method. This finding, and severe non pitting oedema in a fatal case, directed his attention to electrolyte and water metabolism.

At this point he consulted his former teacher, Sir Stanton Hicks, head of the department of physiology in Adelaide University, and a large scale investigation was planned. Clinicians were invited to coöperate by referring their cases to the hospital, and in consequence the earlier finding of lowered plasma sodium was confirmed. Haemoconcentration, as shown by the haematocrit and red blood cell count, was also common, and had in fact been recognised in this condition for some fifty years. There thus emerged a picture of decreased plasma and extracellular fluid volume, sometimes associated with overhydration of the cells.

The milder cases were treated with extra sodium chloride (about 8 g daily), and the more severe cases also had 3 mg deoxycortone on alternate days. The response to this treatment was uniformly good, reducing the average stay in hospital from 3-4 months to as many weeks. The main symptoms of irritability, apathy, and sleeplessness usually disappeared in about 2 weeks, but the extremities might remain pink a little longer.

With such a background Hicks and his group had evolved a theory of "fractional hypofunction of the adrenal cortex" to account for the disease. The maximum age incidence coincided with the period of gross morphological change in the adrenal cortex, in which the adult layers developed to replace the involuting, relatively larger, fetal cortex, at such a transitional period disturbances of function might be especially prone to emerge. In South Australia the allergic diseases of infancy also had a peak at this age. Another theory, which the Adelaide school had earlier favoured, was of functional overactivity of the adrenal medulla. This would explain the tachycardia, high diastolic blood pressure, and common initial fever and excessive sweating, but it did not account for the newer findings of low plasma sodium and the response to sodium chloride and deoxycortone. The infection theory certainly could not be eliminated, but the common occurrence of large tonsils and adenoids might simply indicate adrenal cortical hypofunction. Possible infections brought out symptoms of an adrenal cortical deficiency which was previously latent. The theory of mercury poisoning is still a possibility, largely from confusion due to mercury

in teething powders sometimes given for symptoms which might be those of incipient pink disease

CLINICAL PICTURE

Clinically, the child, aged usually between 6 months and 2 years, was abjectly miserable, with apathy, irritability, insomnia, and anorexia. The skin of the extremities was swollen, sweating, and usually cold. There was a sluggish circulation through dilated capillaries, giving a pink colour in warm surroundings and a cyanotic hue in cold. The skin was continually burning, tingling, or itching, and was hypersensitive to common stimuli, so that warm water felt painfully hot. Such swollen, raw-looking, sweating extremities, sometimes also desquamating and injured by continuous rubbing, contrasted strongly with the dry scaly skin over the emaciated trunk. The muscles were hypotonic and weak, although continually producing writhing and wriggling movements and the tendon reflexes were reduced or absent. Characteristically the child buried his head in the pillow to protect his eyes from the light, and persistently rubbed and scratched his tormented hands and feet. Early on there might be fever as well as tachycardia, raised diastolic blood pressure, coryza, and leucocytosis. For many months after the acute phase the child's health was likely to be subnormal.

RESPIRATORY MECHANISM AND HYDRATION

Fœtal arterial blood was only about 63% saturated with oxygen, and yet the oxygen utilisation reached 75% as against 31% in the mother, whose arterial oxygen saturation was 95%. Armstrong had shown that in animals intermittent anoxia led to adrenal cortical hyperplasia. Furthermore, adrenal cortical extract improved the survival rate of anoxic animals. These facts suggested that in infants with inadequate adrenal cortical

reserve the respiratory mechanism might be abnormal.

At birth the proportion of body-water was only 10% more than in the adult, but the newborn had relatively much more in the extracellular compartment. Bearing in mind that the infant's kidney could not concentrate well, and that glomerular filtration approached the rate in adults only after the first 5-6 postnatal months, the special vulnerability of the infant to factors altering its hydration became understandable. In South Australia mothers tended to limit their infants' salt intake so that, especially in hot weather, there might be actual sodium deficiency, and perhaps this might explain the relatively high incidence of pink disease in this area. Administration of hypotonic saline only accentuated the disturbance, whereas hypertonic saline corrected it. If older marantic children who were having episodes of cyclical vomiting were examined for adrenal cortical hypofunction, a tendency to low plasma sodium might be found, and an unduly high proportion of these patients had a history of previous pink disease. These cases, Sir Stanton suggested, might be due to a milder deficiency of adrenal cortical reserve, and might also respond to treatment with sodium chloride.

STOMATITIS

A vote of thanks was proposed by Dr S. L. SIMPSON and seconded by Prof A. A. MONCRIEFF. Both admitted that some features of pink disease were still difficult to understand. Professor MONCRIEFF mentioned in particular that the stomatitis of the textbook description of the disease was notably absent from its modern form. It was hard to explain the raised diastolic blood pressure on a basis of adrenal cortical insufficiency, and his experience in England had not corroborated the findings of low plasma sodium levels. Possibly the pink disease of Australia was different from that in this country.

Medicine and the Law

The Courts and the Period of Gestation

WITHIN limits carefully defined in legal textbooks our courts confess judicial knowledge of certain simple facts of nature without requiring them to be proved by evidence. In *Preston Jones v Preston Jones*,¹ decided in the House of Lords on Dec. 14, Lord Simonds observed that it had never been doubted that the court had judicial knowledge of the normal period of human gestation.

The normal period, it seems, has been variously stated, it was taken, for example, as 270-275 days in 1887 (*Bosville v Att. Gen.*) and as 273-278 days in 1889 (*Burnaby v Bailie*). Subsequent litigation has taught the judges something about abnormal periods. In the *Gaskill* case in 1921 Lord Birkenhead held that a period of 331 days could not be regarded as impossible in the then state of medical knowledge. In *Wood v Wood*, where there was no medical evidence, the Divisional Court took the same view of a period of 346 days. Early in 1949 the Divorce Court allowed even 349 days to be a possibility (*Hadlum v Hadlum**). As the number of days continued to rise, the judges clearly found it necessary to draw the line somewhere. In the recent *Preston Jones* case the figure of 360 was in effect (though the judges were not unanimous) declared to be on the wrong side of the line.

Mr and Mrs *Preston Jones* were married in April, 1941, a daughter was born a year later. On Aug. 13, 1946, a second child was born. The husband petitioned for divorce in the following November. He contended that this second child had been conceived between Aug. 29, 1945, and Feb. 13, 1946. During the whole of that time he was absent from the United Kingdom while his wife remained here. He alleged that it was not his child and that its conception was the result of an act of adultery. The divorce commissioner dismissed the husband's petition. The Court of Appeal ordered a re-hearing

The case being re-opened. Mr Commissioner Blanco White found that the husband had been absent from the United Kingdom between Aug. 17, 1945, and Feb. 9, 1946. The wife had suggested that her husband had visited her in the intervening November but this the commissioner did not accept. He further found that the birth of the child (which weighed 8½ lb) was apparently normal and that it could not have been begotten as the result of marital intercourse on or after Feb. 9, 1946, the date on which the husband arrived home. The commissioner had then to ask himself whether the fact that at least 360 days had elapsed between the last possible intercourse between husband and wife and the birth of the child, together with the medical evidence, put it beyond reasonable doubt that it was not the husband's child. The commissioner, who apparently found the medical evidence inconclusive, held that he would not be justified in finding that the wife had committed adultery, he dismissed the petition. Once more the husband appealed and once more the Court of Appeal directed a re-hearing. It might it seems, have granted the husband a decree outright, had there not been some question of the admission of certain correspondence at the trial.

By a majority of four to one the House of Lords has now allowed the husband's final appeal and has remitted the case to the High Court in order that the proper decree may be granted.

There remains, however, a further problem of judicial knowledge or ignorance in cases of this kind. By the normal period of gestation the courts mean the time between conception (the union of the male and female cells) and birth. Recent cases have caused the judges to consider the possible interval between coitus and fertilisation. In the *Gaskill* case it was suggested that this latter interval might be so long as 21 days, in the *Hadlum* case one of 14 days was referred to. In *MT v MT*, in the latter part of 1949, when the divorce judge refused to accept the possibility of a normal healthy baby being born after an interval of 340 days between coitus and birth, a gynaecologist had stated in evidence that he had never heard of an authentic instance of an

¹ See *Lancet* 1949 i 586

² *Ibid.* 1948 ii 123

interval of 21 days between coitus and fertilisation Lord Simonds asks if judges can, without evidence, take note of the possibility of some such interval. Can they, without evidence, he asks, refuse to entertain the possibility of a 30 day, 60 day, or 90 day interval between coitus and conception? He thought that ordinary men and women would regard it as a fantastic suggestion that a normal child born 360 days after the last intercourse between husband and wife could be the child of the husband. "It is to me repugnant," said Lord Simonds, "that a court of justice should be so little in accord with the common notions of mankind that it should require evidence to displace fantastic suggestions." In the Preston-Jones case the only medical evidence was that of a doctor whose training and everyday working practice must have made him familiar with the ordinary problems of gestation and birth. This witness admittedly had not studied the problem of the maximum period from the time of coitus to the time of the impregnation of the ovum, but his earlier answers showed that he regarded it as impossible an interval which would defer a normal child's birth until 360 days after coitus. The doctor was, in Lord Simonds's opinion, entitled to give that evidence as a matter of competent medical opinion even though he had made no special study of the subject. The divorce commissioner was not justified in disregarding the doctor's evidence. He was, as a matter of judicial knowledge, entitled to know that there were abnormal cases of gestation as well as a normal period, but he was not entitled to set his own view of possible abnormality, whether derived from the reported legal decisions or from other sources, against the evidence which he had heard. Having found the facts as stated, the commissioner should have acted on the medical evidence and should have granted a decree of divorce.

Parliament

The Minister and Registrars

Light Opposition Members including Dr Charles Hill and Mr Hugh Linstead, have tabled a motion in the House of Commons on the Ministry of Health's proposal to reduce the number of hospital registrars. The motion criticises the Minister's decision, announced in the debate of Dec. 15, to proceed with the proposal during the Parliamentary recess, in view of the strong dissatisfaction expressed with the policy on both sides of the House. The recess began on Dec. 15, the day on which the debate took place, and continues until Jan. 23.

QUESTION TIME

Medresco Hearing-aids

In answer to a question Mr ANEVRN BEVAN, the Minister of Health, stated that deliveries of 'Medresco' hearing aids manufacturers were averaging 8116 a month.

Hospital Registrars

Mr M. C. HOLLIS asked the Minister whether, at his consultations with the representatives of the doctors concerning the issue of the circular on the reduction in the number of registrars in hospitals, the doctors agreed to the issue of the circular. Mr BEVAN replied: "The circular was discussed in detail with the profession's representatives, and modifications were made to meet certain points they raised, but they do not feel able to agree with the final draft in every respect."

Diagnosis of Cancer

Mr G. FRANK MEDLICOTT asked the Minister if he was aware of the delay which occurred in many cases before patients suffering from cancer sought proper medical attention, and if he would take steps to make it more widely known that valuable remedial measures could be taken in many instances if the disease was diagnosed in its early stages. Mr BEVAN replied: "I agree that the facts are as stated by the hon. Member. The Central Health Services Council have been recently advised that it is undesirable at the present time for any further publicity to be carried out by any central government department in direct or indirect connection with the general public."

In England Now

A Running Commentary by Peripatetic Correspondents

THE other week I attended the inaugural meeting of a local poetry society. I knew that all would be well directly my eyes fell on the instigator, a tall smooth young man with a luxuriant jet-black beard. He had two confrères, who were obviously accustomed to reading verse aloud in strong vibrant tones—and did. One of them embarked on a survey of English poetry, starting with Chaucer, the other read short extracts of poetry, as illustrations, I found the Chaucerian rhythms most attractive.

Besides these three and myself, there was the instigator's wife—a pleasant girl with nothing unusual about her—and a middle-aged civil servant with wife completed the party. The wife had no use for poetry, the civil servant had presumably brought her along because he did not want to leave her at home. He said that poetry had always been a passion of his and volunteered to read some, the poem of his choice was "Tell me not in mournful numbers." He read it with dignity, explaining the more ambiguous portions. What a bad poet Longfellow is, and how poorly he expresses himself for example, is the poet telling us that life is an empty dream, or merely that he does not want to be told so in mournful numbers?

When the civil servant had finished, the bearded instigator, out of sheer devilment, volunteered to read Eliot's *Sweeney Agonistes*. It was read with tremendous gusto—gusto is the only word which adequately describes his huge joy in the presentation of this remarkable poem. His two confrères joined in the chorus, which, you will remember, is all about bamboos. I enjoyed it tremendously, though why "I did a girl in, I did a girl in," is considered to be a line of poetry I find it difficult to understand. The civil servant said he did not like Eliot (I am sure his wife, too, failed to appreciate *Sweeney Agonistes*). At this stage I was asked what I would like to read, but I firmly refused to read anything at all.

The setting was in keeping with the proceedings—a small front room in a suburban house—a few chairs (some garden chairs) and two bookcases—a cubist design over the fireplace—a few geometrical figures on one of the bookcases, made of springs, coloured wire, and little spoons—some "mobiles" in the hall—coffee (very good coffee, too) on orange wood tray on floor—two siamese cats, wending their ways in and out among the chairs, climbing up to be fondled and occasionally emitting strange hoarse cries. I shall certainly go again.

Those of us who did our "district" (practical midwifery to you) in London north of the Thames will remember the Regent's Canal as a useful landmark for locating obscure addresses and a source of simple entertainment during waiting periods. Glimpes of the canal can be had in a lot of unexpected places, but not until lately did I have an opportunity to traverse its full length by water. The master of a Diesel engined "narrow-boat," normally trading in the Potteries, asked me to make the trip with him. I had wondered whether time-keeping would be as uncertain on canals as it is on the sea, and I was not left long in doubt. Our speed of progress largely depended on who won the races for the locks, and the master lived in constant fear that a small boy would bob up in a craft on the other side just in time to take possession of the lock.

The journey started in north Hertfordshire following the route well known to railway passengers from Paddington or Euston. The real crossing of London began at Paddington basin, a small tree edged lake as quiet as a Thames backwater. For some distance after leaving the basin the canal follows a road from which I have often watched the boats pass, but now we provided amusement for others until a tunnel swallowed us up. One is conscious of being a source of free entertainment at various stages of the journey, but it is frankly humiliating when passing the Zoo to be stared at disdainfully by rows of cage dwellers, mostly standing on one leg as if they are saying it is their turn now. Opposite power stations and factories you are just part of the everyday life and are passed on with a friendly wave of the arm.

The passage through the Islington tunnel has often

been described. The first thing to do is pray that you will not meet any other boat. All craft have a bow light, but ours was unreliable, so it fell to me to go forward 70 ft. and be ready with a torch for untoward happenings. A friend of mine who had flown to South America in the *Graf Zeppelin* once told me how he felt going along the cat-walks in the aircraft, but that was nothing to traversing what is termed the planking of a narrow-boat in semi-darkness.

The holds of narrow-boats, when filled, are covered to the full width of the vessel with a special form of ridged awning. Along the top of this ridge runs a springy plank 9 inches wide on which you may walk or crawl to the bows. With the torch bearer safely on the tiny fore-deck we entered the tunnel. If you are looking for complete detachment from worldly cares try a trip up forward through a long canal tunnel. One anxiously listens for the steady *ponk-ponk* of the engine, unbelievably far astern, because if it fails there is nothing for it but to pole through. The wet tunnel sides, sooty from tug smoke and diesel exhaust, make this operation much more unpleasant than it was before engines were introduced. The smoky lamp sheds its tiny circle of yellow light and all one can do is hope there won't be a crash with the walls or some other craft. Nothing happened in our trip except that I got increasingly stiff in muscles. I did not know existed. Another lock was negotiated and we came to a region I used to know well, with almost forgotten street names which recalled vivid obstetric experiences of long ago. And not only obstetric experiences came to mind. There was the night of the street fight between two ticket-of-leave men who were always making trouble. There was the celebration when the birth of a much-wanted boy coincided with a highly successful day for the father at Doncaster races. Then there was the jemmy incident, but I digress.

London viewed from its canal becomes increasingly attractive the further east you go. Gardens run down to the waterside and many of them though small are most carefully tended. Then there is Victoria Park, how many Londoners living in W1 or SW5 have ever seen it? Our cargo was loaded for a village in Essex approached by the Stort. For this reason we saw Victoria Park from a new aspect because the cut from the Regent's Canal to the Lea follows it closely. This short cut is tricky to navigate, and at one place we ran aground thoroughly, causing a delay which might have been serious because the short staircase of locks into the Lea, for some unexplained reason, is padlocked at 5 P.M. However, all was well and once in the Lea our progress northward was rapid. Darkness overtook us before we got very far so my memories of the journey end, like an early cinema film, with a slow fade out.

One of the patients at the skin clinic was a little girl with an inconspicuous spider naevus on her cheek. Her mother was a strikingly attractive woman. I asked about her husband's occupation, her other children, her home, her activities. I must own that these questions had more to do with my interest in psychosomatic factors than with the child's naevus, but she answered readily and vivaciously. At the end I was taken aback when she asked, "Well, Doctor, you have been asking me questions, do you mind if ask you a few?" And she did. Where was I born? Married? Children? How had I come to take up medicine? Was I happy in my work? That woman must have enjoyed her surprise counter attack. Why have I never thought of turning on my inquirers? There was that M.R.C.P. examination when a distinguished paediatrician questioned me on what I considered to be an intricacy of his specialty. Why didn't I say, "All right, Sir, that is one up to you. Now, would you care to discuss the differential diagnosis of the premycotic stage of mycosis fungoides?" I suspect that his difficulties might have been as great as mine had been. Then there was the interview for an appointment in which I was asked what contributions I had made to dermatology. I might have replied, "The few projects I have in mind will take several years to mature. What original research have you done, Sir, in the last twenty years?" Which of us would have had more reason for embarrassment? But I am still going up for jobs, whereas this mother had nothing to lose.

Letters to the Editor

GENERAL PRACTICE

SIR,—Dr Lennox Johnston's letter in your issue of Dec. 16 very feelingly emphasises the unsatisfactory state of general practice today. The growth of medical knowledge and techniques has made the general practitioner's surgery something of an anachronism, and the health service, with its offer of bounties to the patient, has made the practitioner the servant of the public in the wrong sense. This would not have happened if the practitioner had been able to offer himself in his true rôle of observer of diseases in its earliest stages, adviser on the maintenance of health and the details of treatment, an interpreter of specialist opinion. He has rarely the time to fill these rôles, and certainly if he has time he cannot make an adequate living in the National Health Service. The essence of the whole problem is time.

This can only be provided by protecting him from the patient who comes for some return for his weekly expenditure. We all hear too often "I have to pay such and such a week, and I may as well have something for it" and often this is not said but understood. The practitioner must also not be tempted to take on more work than he can do. Who can say No to more work and more money, especially in these difficult times?

We are loth as a profession to part with the competitive system because we feel it puts a man on his mettle but I am not sure that this is true today. The salaried service has its dangers, but I feel we must ask ourselves which method now has the least evils. The problem is not easy, but I feel it is in need of urgent attention if general practice is to be saved and the practitioners to regain his honoured place in society. I think there is no doubt that the community would be the worse without him, and I believe that if the monetary reward could be divorced from the total of patients we should all become better doctors. There appears to be a feeling that if we were not paid so much per patient we should become less sympathetic to our patients' troubles—as if much devoted care was not given before the day to those who could never hope to pay. The quality of sympathy and understanding are of the man and not the system.

Blackburn

FRANK LIVESLEY

THE CHANGING FACE OF SURGERY

SIR,—In his address to Westminster Hospital Medical School (*Lancet*, Dec. 9) Sir Cecil Wakeley shows great prejudice against the concept of whole time clinical professorships. He is perfectly entitled to his opinion but it is unfortunate that he should choose to express his disapproval to medical students with the use of fallacious arguments. We have no means of assessing what work Lister would have done as a whole time clinical professor, any more than we know what Job Hunter's output would have been as professor of pathology at Oxford. These men did their work because of the urge to do it, and not for financial reward. Provide the time in which they lived was not one of oppression towards all original work, these men would have been notable whether as whole time or part-time professor. The man can be superior or inferior to the appointment he holds.

It is equally wrong to suggest that the whole time clinical professor of surgery must be cut off from the general practitioner. In quite a few universities the whole time clinical staff have the option to do domiciliary consultations (but of course do not receive a fee). If the whole time professor declines to do domiciliary consultations, that is a loss for the individual and not a fault of the system.

No system is perfect, and the criticism that a part time professor of surgery might be out of touch with the laboratory is just as valid as that the whole time man might be out of touch with the general practitioner. In both cases the opportunity is there. As yet it is much too early to decide whether whole time clinical chairs produce a higher standard of work—after all it is only about ten years since the institution of such chairs in any university. The president of the Royal College of Surgeons has a great responsibility, and his opinion rightly carries great weight. It is therefore most disappointing that he should be so damning towards an experiment which has only just begun.

Medical School Dundee

JOHN GRIEVE

SALICYLATE AS AN ANTICOAGULANT

SIR,—Dr Gibson's letter of Dec 9 prompts me to refer to the article¹ in which he recommended a combination of aspirin with ascorbic acid and tragacanth as an anticoagulant in coronary thrombosis and angina of effort.

There are some rheumatic patients whose treatment is complicated by attacks of phlebitis, with or without obvious thrombosis. In these cases Dr Gibson's formula is most valuable, as it not only prevents thrombosis but also relieves the rheumatism. As Dr Gibson points out, when the mixture is given with food there is no gastric disturbance.

London W 1

H WARREN CROWE

PHILOSOPHY OF CLINICAL MEDICINE

SIR,—In his lecture on the psychosomatic approach to clinical medicine, Dr Ranyard West² raises important questions and suggests an answer. Most people will agree that when the same patient can be treated with kaolin on Thursday and by a psychological probe on Monday, clinical medicine has reached a state of theoretic confusion and of therapeutic chaos. In this note I suggest that the cause of this state of affairs is that clinicians are over simplifying the clinical situation and therefore failing to make necessary distinctions in clinical diagnosis and treatment.

The practical usefulness of the psychosomatic approach is not questioned, but we must ask whether that approach does not break down in practice, at the same point at which physical and psychological medicine break down—namely, when "the clinical case" transforms itself into a "living person". A person is not a hyphenated body mind, of which fact Dr West is aware when he writes "it is often the patients rather than their doctors who succeed in adapting themselves to two conflicting philosophies of medicine". How does it happen that patients can reconcile, without instruction, incompatible opposites that defy the best minds in our profession?

Sherrington has shown *where* the integration of these opposites is achieved, even if he has not stated clearly *how* that integration is achieved. It takes place "in the process of living. Life psychically experienced and life physically experienced become 'one life and one experience' in the awareness of the 'one life and one experience' in the awareness of the 'self' that he is in fact an enduring entity an 'I'". It has been objected that few people are aware of their continuing self identity, but, as Sherrington says elsewhere, this is due to the nature of conscious mind which has been evolved to meet practical situations and not in the interests of self awareness. The mind is able to attend 'to only one main task at a time'.

It seems then that, as clinicians, we may be taking the "self as a unity" for granted, and studying only the 'self in its manifoldness'—i.e., its organs, functions, cells, and complexes. Hence we have failed to grasp

the clinical significance of those diagnostic factors and those therapies whose value depends upon their origin in, or their effect upon, the unity of the personality. A. N. Whitehead has said that the problem before philosophy is to provide a satisfactory doctrine of personality and of the facts of the continuing self-identity of the organism. Doctors face this problem as a need for a coherent theory and practice of personality diagnosis and therapy.

W. D'Arcy Thompson and his school make the same point. Having demonstrated the significance of the *form* of the living organism in all biological theory, they have shown that the form (i.e., the self identity) of the organism largely determines the particular shape that the organism will assume, at each stage of its life cycle. C. G. Jung makes the same point—as is well brought out by J. Jacobi in her study of Jung's work. By insisting upon the significance of the "formal" causes of mental behaviour as well as upon the "efficient and final" causes of it, Jung makes an important practical distinction. Some students of Freud hold that the doctrine of the super ego, if followed to its logical conclusions, leads in a similar direction. The increasing importance attached to "purposes, life aim and life styles" by other psychologists reveals a similar trend. Many general practitioners are realising that the "disorders of personality" are of great practical importance in clinical medicine in general, and in the preventive diagnosis of illness in particular. It seems reasonable to suggest, therefore, that a concerted attempt should be made to separate the "formal" or "personality disorders" (together with their clinical antecedents and consequents) from the many syndromes, &c., that have been distinguished hitherto solely by paying attention to disorders of the "manifold"—i.e., the psychosoma, or the body, or the mind (when this has been viewed as an "organisation of instincts").

Following this line of thought, some of the more obvious disorders of personality—sometimes called disorders of "attitude"—can be indicated.

1. There is a large clinical group of patients who manifest syndromes of despair. The basic psychology of this group was discussed by Kirkegaard many years ago. In practice three clinical varieties of this syndrome can be distinguished: (a) the despair of ever becoming an individual which is the commonest personality disorder of the young; (b) the despair of ever becoming a self (i.e. an integrated personality) which is the commonest personality disorder of those under, say 35–40 years of age; and (c) the despair before death (also called the eternal despair) to which Dr West seems to refer when discussing the 'death acceptance instinct' and which, as Jung insists is the psychological disorder par excellence of middle and later life. All of these despairs are unconscious. Whenever they are made fully conscious, they are in a fair way to being cured as a rule.

2. The major syndromes produced either by an arrest or by a repression of normal personality evolution are also well recognised. They are accompanied by recognisable effects and by certain peculiar disturbances of the normal awareness of self identity and of the normal awareness of reality. Examples of the personality regressions are to be found in every mental hospital.

3. Again certain critical ages in the normal evolution of the personality are recognised. These are age periods during which arrest or repression are most liable to occur and they mark periods of transition from one stage to another in the evolution of the integrated personality from its early antecedents in the innate character of the infant. Childhood, adolescence, maturity (about 35), and middle age are the dangerous ages in the evolution of the personality. If we agree to call the innate form of the infant by the name 'character', then the integrated mature personality may be said to be the form of the mature adult and so on. In this sense character is innate, while personality is in part determined by innate qualities and in part by experience.

All attempts hitherto made to isolate a group of basic instincts, complexes, or sentiments, capable of

¹ Gibson, P. C. *Lancet* 1949 ii 1172
² West R. *Ibid.* 1950 i 1025

serving as a sound theoretic basis for the diagnosis of personality, seem to have proved unsuccessful. The same is true in the field of social psychology where the hopes raised by Pareto's original analysis seem to me to have faded. Similar failures attended the efforts of the old faculty psychologists and of the system physiologists (as J S Haldane insisted). I suggest, then, that all of these failures have arisen from the same cause—namely that attention has been concentrated exclusively upon the manifoldness and not upon the unity of the self, upon the psychosoma and not on the personality.

On the practical side, this new approach to medicine offers the clinician the help of a number of "therapies of personality" (as the Americans term them). At one extreme those include suggestion, prestige therapy, and the morale therapies. They include also a wide variety of therapies by occupation, by arts, crafts, and play, also some new group and social therapies that are now being actively studied, and, of course, education, persuasion, and other methods of personality healing. Finally there is a group of therapies of which more may be heard in the future—namely, various specifically religious therapies all of which call for careful study by clinicians.

The importance of revising medical theory and practice in the direction here proposed can hardly be over-emphasised. The new approach will be found to complete, rather than compete with, established clinical methods. If I am right, it will clear up the prevalent intellectual muddle, enable the general practitioner and the specialist to work together towards a single end, open up new avenues in therapeutics, and bring medicine into line with recent advances in biology and philosophy.

Worcester

HOWARD E COLLIER

CEREBRAL PALSY

SIR,—I am sure that no articles which you have published have contributed more to the understanding of each disease as a problem affecting all aspects of the patient's life—physical, psychological, social, and financial—than have those in your excellent Disabilities series. Of these, none has made a deeper impression on me than that on cerebral palsy (Dec 16).

Here is a disability which is seldom treated by parents or friends with understanding, and no wonder, since even the neurologist may find difficulty over the details of diagnosis. It is perhaps because of this uncertainty as to the problem to be tackled that orthodox medicine has in the past paid so little attention to the final and, in the end, the most important question: What can be done? It is appalling that an adult woman should be able to report that only "within the last two years

—I have benefited from specialised cerebral-palsy treatment." Previously, she had helped herself laboriously through inarticulacy to speech, and through uncontrolled movement to the achievement of functionally adequate, though slow and awkward, performance. Surely the fact that she has benefited from her recent specialised treatment suggests that an understanding of the nature of the disability may, with our present knowledge, form a useful basis of treatment.

This article can leave no doubt in the mind of any reader as to the possibility that a patient with cerebral palsy may yet be highly intelligent. It is a sobering thought that others, with less inspired parents, with only a little less intelligence or determination, or with a slightly more severe disability, fail in the struggle for lack of skilled help, to pass their days excluded from all society in a back room or incarcerated in a home for mental defectives.

Much is already being done, and local authorities are now obliged to provide for the education of every child capable of benefiting. But without highly skilled guid-

ance such education can do little to make these children socially acceptable, and so will be largely wasted. Our aim should be to undertake treatment of these children from the first moment in infancy when abnormality can be detected, when their adaptability is greatest, so that as many as possible may, by school age, be fit to go to normal schools without the disadvantages described by your contributor, and so that no intelligent child need exhibit unintelligibility, drooling or others of the grotesque handicaps which often militate against social acceptance or employment.

So far only one hospital has undertaken, through a research unit and an advice clinic for parents, the difficult task involved. The value of its work, only now becoming appreciated, gives us a pointer to the future.

GERMAN MEASLES IN GIRLS' SCHOOLS

SIR,—Mr Robinson (Dec 16, p 827) appears to have overlooked the possibility of one of his daughter's school friends having a pregnant mother.

Silver End, Essex

J W NICHOLAS

STUDY OF DELINQUENCY

SIR,—One sometimes doubts whether it takes two to make a quarrel, and I have no wish to offer myself as a protagonist, particularly as I some time ago published views which largely agree with Dr Stott's. Thus "The reliable report is based on painstaking, sometimes even tedious, collection of data. There is no short cut. We have no crystal ball." And "Where the psychiatrist has insufficient time to study his cases and to interview the parents, the magistrate will be justified in considering that as good a guess may be made in the court room as elsewhere." In the same paper psychiatrists are urged to follow up the results of their recommendations and to be prepared to modify the treatment after placement away from home. These and other points, such as the use of psychiatric jargon and loose terms, and many more not mentioned by Dr Stott, have been dealt with in lectures for some years. I find having made a lot of mistakes a good basis for teaching.

I would, however, like to take up the point made by Dr Stott (Nov 25) about treatment being too "clinic centred." With this I agree, but he also says in this connection "A refusal to treat, or a picking or choosing of our patients, will only damage our reputation among the magistrates." In my experience with both juvenile and adult court work, precisely the opposite obtains. The magistrates, and any other experienced workers in the field, know full well that in the present state of our knowledge only a proportion of seriously delinquent cases are amenable to clinic treatment. I believe magistrates simply want to know if a particular case will respond at home with help, or whether some other course must be taken. They will therefore appreciate a frank statement upon the matter, they do not these days expect the clinics to perform wonders with impossible material. Dr Stott reports two hearsay cases in which clinicians refused to see cases which were "too bad" and "uncoöperative" respectively. This, as he reports it, sounds very shocking. But if the two clinicians had in fact declined to treat the cases in their clinics because they appeared unsuitable for such treatment, and if they indicated what other course should be adopted, then these ignorant clinicians might after all be quite sensible people.

We are asked to "imagine what would be said of a family doctor who refused to treat a patient because he did not respond to his one and only prescription." But this is unduly difficult to imagine, because the training of family doctors (like that of psychiatrists) provides

them with a range of treatment methods and encourages them to use inpatient or residential care when the illness is severe or the home deleterious

Anyway delinquency is a big field and there is lots of scope for workers of different trainings to work together, as in fact they seem to do quite successfully

London W 1

PETER SCOTT

RUPTURE OF ASCENDING AORTA

SIR,—Your issue of July 8 contained an interesting report, by Dr Jokl and Dr Mackintosh of a case of rupture of the ascending aorta. I encountered a similar case at St Alfege's Hospital, Greenwich

The patient a married woman aged 24 was dead when brought to the hospital. The relatives stated that she was three months pregnant and had one child aged 18 months who suffered from heart trouble. At 11.15 p.m. after taking two glasses of ale she went to the lavatory where she collapsed. She was found unconscious and did not regain consciousness. When seen in the ambulance two and a half hours later at 1.45 a.m. there was no sign of life.

Post mortem examination showed gross oedema of the lungs with subpleural ecchymoses and on the left some interlobar adhesions. The heart did not seem enlarged but the myocardium appeared anemic, no abnormalities of the valves were noted. The ascending aorta was dilated forming a wide aneurysmal bag, the inner coat of this section of the aorta was in places detached from the media. Two tears were visible one penetrating to the adventitial tissue but not perforating and the other leaking into the pericardium which was filled with large blood-clots. The descending aorta was much narrowed the circumference measuring only 2 cm. No signs of atheroma were found. The uterus and embryo corresponded to a pregnancy of eighteen weeks, the placenta and corpus luteum appearing normal.

I have to thank Dr B. A. Young consultant physician to St Alfege's Hospital, Greenwich for the details of the case and for permission to report it.

R. SCHEUER-KARPIS

MASS RADIOGRAPHY

SIR,—Dr Hoffstaedt's article of Dec 9 is based on a fundamental misconception—namely, that "one unit can manage 25,000–30,000 miniature films a year."

Most units find it possible to make about 50,000 examinations annually. We are not surprised therefore, that the units to which he refers appear to be so expensive. Unfortunately in your leading article of the same issue Dr Hoffstaedt's experience has been applied to mass-radiography units as a whole. Because a Durham carpenter bruises his thumb we see no reason why hammers should be withdrawn from the rest of the country.

You state that mass radiography is expensive. One of our units in south-east London has discovered 250 cases of active tuberculosis during a year, at a cost of £24 each. Surely early diagnosis is the most important facet of the whole tuberculosis problem and should therefore be the last item on which to economise. You further claim that often a number of people are found to have tuberculosis, already cavitating, who a few months or weeks before gave a normal radiograph in a mass survey. Is there statistical evidence to put mass radiography out of court on this point?

You suggest that mass radiography should be applied only to certain selected groups where a higher proportion of positives can be expected than in the general population. Of the groups you list school leavers have an exceptionally low proportion of active tuberculosis—0.15% of 500,000 examined. School staffs, others in contact with children, prospective employees, and women attending antenatal clinics will give no greater yield than others in equivalent age-groups in the population at large. Those with a dust hazard, chronic sick, suspects referred by doctors, and contacts though

producing a higher yield, will do little more than whet the appetite of a voracious unit doing 50,000 examinations in a year. For instance, there is a London chest-clinic area where 996 contacts were examined at the clinic in 1947, representing but two days' work for a mass radiography unit. Much time may be wasted in organising surveys for small groups. We believe that the main emphasis should be on volunteers from the general population.

MEPHENESIN IN PSYCHIATRIC CONDITIONS

SIR,—Mephnesin ('Mvanesin') was originally introduced as a muscle relaxing agent during anaesthesia, being administered intravenously for this purpose. Subsequently, it was found that it produced muscular relaxation in certain spastic and hyperkinetic disorders associated with a variety of neurological conditions, and that it was possible to obtain this effect by oral administration. During the clinical investigation of the neurological properties, it became obvious that it also exerted an effect in the psychiatric sphere, the therapeutic response obtained in cases of anxiety and depression being very marked.

Schlan and Unna¹ treated 63 patients suffering from anxiety states, acute and chronic psychoses, alcoholism, and drug addiction. The dosage of mephnesin was 0.5–1.5 g four times daily by mouth. Patients suffering from anxiety obtained relief within one hour of administration and thus persisted for not less than two hours. Beneficial effects, particularly the abolition of gross tremor were also observed in cases of prolonged alcoholic intoxication. In cases of addiction to morphine and heroin, mephnesin was found to alleviate withdrawal symptoms, such as nausea, leg cramps, and vomiting, most successfully. It frequently produced normal sleep in patients whose disturbed psychic function had been causing insomnia. Henneman et al.² believe that it acts by raising the threshold of internuncial neurones in the spinal cord and brain stem.

It is with the object of making the valuable properties of mephnesin more widely recognised that the following cases are reported.

CASE 1—A 47-year-old male dipsomaniac was given 'Mvanesin Elixir (B.D.R.)' to relieve tremor. Two weeks after he left the nursing home I was called suddenly to see him by a member of his family, the impression being that he was suffering from the effects of alcohol. He had in fact taken an 8 oz. bottle of the elixir on each of three successive days; his speech was slurred, his movements were awkward and clumsy and he was mentally retarded. He was almost incapable of standing and had to be supported when walking. His reflexes, pulse and blood pressure were not appreciably affected. He subsequently found that in therapeutic doses mephnesin effectively relieved him of his craving for alcohol.

CASE 2—A 44-year-old woman who had attempted suicide suffered from intractable restlessness and insomnia. Paraldehyde made her violently sick and had to be discontinued. Many other hypnotics were equally ineffectual. 1 oz. of mvanesin elixir was prescribed preceded by 'Tunal' gr 3 thirty minutes earlier. This combination produced refreshing sleep for ten hours.

CASE 3—A 35-year-old man in receipt of a 20% disability pension for psychoneurosis, suffered from epileptic fits which did not respond to anticonvulsant or other drugs. Mvanesin elixir was prescribed in doses of 1 oz. when the aura of tingling developed down the left side of the body merely in an attempt to relieve the intensity of the fits. Since the first dose there has been no recurrence of fits now extending over a period of several months during which time he might have been expected to have had dozens.

¹ Schlan L. S. Unna K. R. J. *Amer med Ass* 1919 140 672.
² Henneman E. Kaplan A. Unna K. R. *Fed Proc* 1949 8 301.

CASE 4—A woman of 34, with a grossly unstable personality, was subject to hysterical outbursts of manic intensity. She was instructed to take myanesin elixir (1 oz) when she or her husband felt that an attack was impending. This has been completely effective. She describes the effect of mephenesin as similar to mild intoxication: she is "knocked out" for a couple of hours, after which her aggressive episode has passed. Her entire personality has changed since her outbursts have been controlled. She has become psychologically accessible, less inhibited, more objective in her outlook, and a happier person.

CASE 5—A man of 52, who had been invalided out of the Army on account of myocardial degeneration and hyperthyroidism, applied unsuccessfully for a pension. Two specialists decided that there was no evidence of the disabilities on account of which he had been discharged from the Forces, but when they identified an anxiety state he became very apprehensive. Anxiety attacks, characterised by trembling, palpitation, giddiness, and fear of collapse, occurred almost daily, and he became unwilling to go out of doors except by car. Myanesin elixir was prescribed, after sedatives had failed to effect any improvement, and the severity of his attacks was immediately reduced.

I should like to express my thanks to the directors and staff of the British Drug Houses for their coöperation in this work.

ELLIS STUNGO

DOORMATS FOR OPERATING-THEATRES

SIR,—It has often struck me that the amount of contamination introduced into the operating theatre on the soles of nurses', surgeons', visitors', and porters' feet must be quite considerable, and I venture to suggest that a certain amount of antiseptic cleansing of the soles of shoes and wheels of trolleys could be achieved if a sunken, floor level, padded mat, soaked in a suitable antiseptic, could be placed at the common entrance to an operating theatre suite.

Anyone passing over this mat would automatically coat the soles of his shoes with a thin layer of antiseptic, in the same way as "foot and mouth" traps are situated at certain frontier posts in Europe.

Buckhurst Hill, Essex

BERNARD KAPLAN

HEPATIC ABSCESS ASSOCIATED WITH SCHISTOSOMIASIS

SIR,—I have only lately had the opportunity of reading the article on this subject by Dr Graham and Mr Orr.¹

Infestation of the liver by schistosomes has been recognised for a long time. In 1933 Bourguignon, in Elisabethville, showed me some beautiful photomicrographs of adult worms and eggs in the liver.

The population around this hospital shows an infestation rate of 16% with *Schistosoma haematobium*. This is after a single examination, repeat examinations would give a considerably higher rate—possibly double.

Palpable livers are common, both in small children and in adults. In almost all children with palpable livers schistosome eggs can be found by repeated urinary examinations. In adults enlargement of the liver is commonly accompanied by enlargement of the spleen and ascites. These cases usually terminate fatally in a few years or less. Sometimes the liver has become shrunken and cirrhotic before death, in such cases schistosome eggs can often not be found in the urine, but cystoscopy often reveals extensive damage of the bladder wall. I conclude that either the worms have died or that the extensive cicatrization prevents the escape of the eggs.

On the other hand, liver abscess from any cause is rare here. I have seen only 2 instances in 120 autopsies and in a large number of explorations either by operation or puncture. The suggestion by Graham and Orr that in their case the abscess was caused

by auto infection of a necrotic area appears to me very probable. They are to be congratulated on giving us a timely reminder of schistosomiasis as a possible cause of hepatomegaly and liver abscess.

PATRICK K DIXON

STRIE CUTIS DISTENSÆ

SIR,—May I summarise some of the points arising out of this controversy?

(1) Striae atrophicæ (I use this term because striae may occur without any previous stretching of the skin) are an expression of damage to the skin.

(2) Sixteen years ago I thought that purple striae atrophicæ were characteristic of Cushing's syndrome due to basophil adenoma.¹ I abandoned that view because they occur with adrenocortical tumours causing Cushing's syndrome, and disappear after removal of the tumour (Selye,² p 170). Furthermore, there are typical cases of Cushing's syndrome with no striae, in spite of rapid increase in weight. Spence demonstrated an example to the endocrine section of the Royal Society of Medicine on Nov. 22. A woman of 47, with a mixed Cushing's and adrenogenital syndrome due to adrenal cortical carcinoma, had a petechial eruption over her upper chest, neck, and arms, and yet had no striae atrophicæ. Her excretion of urinary 17 ketosteroids was 42.5 mg per 24 hours. Only 4 weeks ago I saw a case of the pituitary type without any striae in spite of an increase of a stone in weight within 4–6 weeks at the beginning of the illness.

(3) Patients may develop purple striae in association with pleural effusion, pulmonary tuberculosis, pneumonia, asthma, dysentery, or tonsillitis, and even without any signs of illness.^{3–5} (e.g., three cases reported by Hurford and Snell³ and one by Parkos Weber⁵). In Parkos Weber's patient they were present from 1934 to 1942, although the girl remained in good health (see Romer⁷).

(4) Cases of chronic malnutrition sometimes develop such striae.^{6, 10}

(5) Overdosage with Cortisone or ACTH may produce striae atrophicæ as well as hyperpigmentation, acneiform eruptions, hirsutism, rounded (moon) face, delayed wound healing, and flattening of keloid scars.¹¹ In the New York conference on ACTH, Sprague¹² stated that the hyperpigmentation resembles that of Addison's disease. Behrman and Goodman¹¹ accept Albright's view that the striae are caused by thinning of the skin due to protein depletion. Selye¹⁰ confirms that the same hyperpigmentation may be found in severe adrenal cortical deficiency, he says, "if systemic overdosage with cortisone may render the rat skin extremely atrophic and transparent, so do hypophysectomy and adrenalectomy", finally, he finds it "suggestive to assume some interrelation between the characteristic striae of Cushing's disease and the cutaneous atrophy which occurs in debilitated individuals and after overdosage with cortisone or ACTH".

(6) Purpura may occur as a result of damage to the capillary endothelium with or without concomitant alterations in one or more of the factors concerned with blood coagulation. It may occur in infectious diseases, after drugs in cachectic states in Cushing's syndrome, after overdosage with cortisone, or from mechanical causes (e.g., in pertussis).

(7) Of hyperpigmentation Selye writes, on p 170 of his textbook²: "sometimes there is a melanoderma (in hypercorticism) reminiscent of Addison's disease. This may be either generalised or patchy, it is not due to secondary destruction of the adrenals since it can appear even in patients in whom only one adrenal is affected. It is also noteworthy, though unexplained, that most animal species

unlike man, do not develop cutaneous pigmentation under the influence of hypocorticism although pigment formation in animals is dependent on the adrenal cortex and can be influenced by corticoids.

(5) The urinary corticoids are usually much increased in Cushing's syndrome and after overdosage with cortisone or A.C.T.H.^{12, 14} but they appear to be decreased in chronic malnutrition and in Simmonds's disease (Selye¹⁰ p. 223). Besides the 'normal' values of urinary corticosteroids vary from 0.5-1.5 mg.¹⁵ and 0.025-0.085 mg. per 24 hours¹⁶ to 0.5-5.0 mg. per 24 hours (neutral fraction) and 0.3-3.3 mg. per 24 hours (water soluble fraction).¹⁷

What does all this mean? Surely that the skin as a target organ responds to a variety of stimuli. In Hindus, melanoderma (even of the mucous membranes) is racial (genetic), in Addison's disease the skin often responds in man and becomes pigmented, the skin of the laboratory animal does not do so.

Patients with localised myxoedema of the skin over the tibia do not seem to have a general deficiency of thyroid hormone, for their remaining skin appears normal. In partial acromegaly only a small fraction of the skeletal system may be affected: there does not appear to be a general excess of anterior lobe hormone particularly of growth hormone.

Bauer¹⁸ has been teaching for many years the 'principle of triple safeguard'—that many traits and functions of the organism are dependent on and regulated by the proper cooperation of (a) the particular organ ("effector organ," *Erfolgsorgan*), now called 'target organ', (b) the endocrine system, and (c) the nervous system. He contends that many traits and functions should be regarded as complex biological mechanisms. They cannot be understood merely by considering single parts of the highly integrated system of individual constitution.

I do not think, therefore, that we are justified in assuming that striae atrophicae are *always* an indication of excess of adrenal cortical hormone. Selye puts it quite clearly in his book on stress¹⁰ (p. 783): "Diseases of adaptation do not necessarily result from an absolute deficiency or excess of corticoids."

I shall end with a quotation from Bauer¹⁸ (p. 54). "It is possible today to produce artificial acromegaly and gigantism in dogs by prolonged administration of pituitary growth-promoting hormone, and it is possible to produce dwarfism by removal of the pituitary or thyroid. It is impossible, however, to transform one canine race into another by means of endocrine control. An artificially produced giant dog is neither a St. Bernard nor a Great Dane."

CHANGES IN THE CENTRAL NERVOUS SYSTEM DUE TO ELECTROCUTION

SIR.—It is perhaps rather late to comment on an article published some sixteen years ago, but the hypothesis put forward then has found its way into at least one medical textbook.

Dr. Blake Pritchard,¹⁹ writing on changes in the central nervous system due to electrocution, suggested that electrostatic forces play an important part in causing lesions in the central nervous system, and supporting this hypothesis by some calculations based on one impossible assumption—namely, that a charge of 0.2 coulombs can accumulate (if only for a short while) on the human body. This charge concentrated on a body of the size of man would correspond

to a potential of roughly 10,000 million volts. In actual fact this is impossible because the surrounding air would have broken down long before such a charge was accumulated and the potential reached. The conclusion therefore that a force of 4×10^{13} dynes or some 40,000 tons, act on the body is not tenable.

Later in the article the kinetic energy is equated with this force which is dimensionally wrong.

Finally the conclusion that a surface charge corresponding to 'half an atmosphere pressure' leads to a decompression wave is untenable. The highest possible electrostatic surface pressure in air is about 400 dynes per sq. cm., corresponding to a break down voltage gradient of 30,000 volts per cm. This pressure is very small indeed—equivalent to the change of atmospheric pressure when jumping from a table to the ground (3 ft). It cannot possibly lead to lesions inside the body.

One of the main reasons for writing this letter is to draw the attention of the medical profession to a useful field of joint research with physicists and possibly engineers.

CENTRE FOR TUBERCULOUS STUDENTS

SIR.—Though such centres are well known abroad and though the need for such a centre has recently received recognition in the B.M.A. Report on Tuberculosis, there exists in this country no particular institution in which students with tuberculosis can receive medical treatment while continuing their studies. The British Co-ordinating Committee for Student Health* is organising a trust fund with the primary object of establishing such a centre, and the committee would, through the courtesy of your columns, like to invite donations large and small to this fund.

It is quite impossible at the present moment to set up a full scale sanatorium treating students in all stages of tuberculosis. It is intended that the centre now proposed should cater for students already sufficiently recovered to be able to take advantage of the educational facilities that it is part of the scheme to provide. It is at this stage that occupational therapy—and for a student his education is occupational therapy—is of most help, it is at this stage that the present inability to continue his studies is most disheartening to the student and, most conveniently, it is at this stage that the demand for skilled nursing is least. Even from the point of view of the treatment of tuberculosis in the non student population, the centre is likely to prove an asset since the transfer of students to the centre from sanatoria would lead to the earlier freeing of sanatorium beds.

The arguments for setting up a centre especially for students apply not exclusively to those usually understood by that term and for this reason it is intended to make the centre available to senior as well as junior members of universities and other institutes of higher education, to research students as well as undergraduates to university and college teachers as well as those in statu pupillari.

All donations to the fund should be sent to one of us, c/o British Student Tuberculosis Fund, Tavistock House South, Tavistock Square, London, W.C.1. Cheques should be made payable to the British Student Tuberculosis Fund.

REGISTRARS

SIR,—In all that I have read about the registrar problem there has been no mention of the junior hospital medical officer. Surely the original fault lay with the hospitals which competed against each other for junior staff by advertising all positions as registrar grades. This was inevitable when a house officer post remained empty until it was rechristened "junior registrar."

The present problems might be solved by limiting the registrar appointments to those hospitals which could offer their staff (or selected members of it) either formal training or adequate free time for study. All other posts would be called house officer or J.H.M.O.—the latter not being limited to a fixed period of years. The man who hoped to become a consultant could then trade his security for greater opportunities of training. If he failed at one stage or another he could remain in his specialty (although probably at a different hospital), as a J.H.M.O. but would have lost his privileged position. If there were a free interchange between the parallel hierarchies, there would be no feeling that the man who left the registrar stream could never become a consultant (although his chances would be less), that is the selection would not necessarily be made at an early age.

Maudsley Hospital London SE 5

OCCUPATIONAL THERAPY

SIR,—In rehabilitation much has been said about the importance of returning the individual to a "work environment." In the case of a machine operator, this implies an industrial workshop where he can be engaged on some machine even though his efforts produce a quantity of material of insignificant economic value. It is in this direction that it seems a creative social function of rehabilitation may be lost.

The value of occupational therapy in rehabilitation is twofold: first, it stimulates interest, and secondly, it restores function and skill. An individual recovering from injury or sickness may on discharge from hospital be unfit to proceed at once to rehabilitation in the form of learning a new trade or recovering lost skill in his old occupation. In this condition, introduction to a well equipped occupational therapy department staffed by personnel with the right outlook may be a step of great importance. There he will see others with a great range of handicap working at one of twenty or thirty different crafts, involving the use of a variety of machine tools. According to the estimate made of his mental and physical condition, the occupational therapist, guided by physician or surgeon, may allow him to choose one or perhaps two jobs—one if that serves to stimulate interest and restore function, or two where one particular job has a major attraction of interest and the other restores function. Often, the interest aroused may be such that without noticing it the patient recovers a greater degree of general mobility than he had thought possible, or, in some cases, even wished for.

Many patients coming for rehabilitation have passed a somewhat drab and unimaginative life at the work bench or in a circumscribed factory environment. To be returned as soon as possible to an industrial workshop may be to lose a great opportunity, almost as though the man was to be returned to blinkers and harness efficiently to draw the cart or tread the corn. In an occupational workshop he will see for the first time the range and number of small crafts to which his hand may be turned for sheer pleasure and joy in creation, perhaps with the added gratification of gifts for friends or furnishing for his home. His vision is enlarged, and when his recovery is complete or he is fit to proceed for

training in a permanent occupation he has learnt craft which can provide a hobby for the rest of life. He has been introduced to a socially creative factory bench which will soon be reached again, but time should never again be lacking in pleasing occupation, and his work at the factory may thus prove irksome. Whether this is so depends to a great extent on the personality of the occupational therapist and his power to instil enthusiasm at the beginning.

It seems that here is a thread in a pattern which might be for industrial workers compensation: routine and monotonous mass production work at all schools where there were well equipped crafts departments, and that in every community were equally well-equipped centres under the experts—centres where materials and tools obtained and the work done in an environment with the space lacking in the modern small lodgings. Here skills might be learned or continued from school. Mother, father, and children collaborate or follow their individual lines. The or sick during convalescence might learn or develop in the occupational workshop and continue in the community workshop.

Stimulated on a national basis with strong community support, these centres might go far to restore a sense of creative activity of the old craftsman, assuage the unrest produced by repetitive work routine jobs or semi-automatic machines—a fact of undoubted importance in producing industrial peace. These centres would provide an alternative to the cinema, the dog, or the cinema so often visited from boredom. The immense difficulties in the way of achieving a development of this sort are realised, but perhaps now that rehabilitation centres and school workshops are being steadily increased in number the idea may be studied and more consideration be given to the creative social function of occupational therapy to offset what is an industrial atmosphere.

STETHOSCOPES

SIR,—There seem, curiously, to be very few capable of giving a simple and coherent account of the stethoscope. I have yet to see in any textbook a discussion of the relative merits of the diaphragm bell types—although their makers must be well aware of the basic principles of the instrument.

It is well known that low frequency notes, such as normal diastolic rumbles, are best heard with the open bell endpiece, and that harsher high pitched notes are clearer when a diaphragm endpiece is used, or a bell is pressed hard on the skin. The acoustic condition system in the case of the chest consists first of an air space separating viscous and thoracic wall, then the "diaphragm" made up of layers of muscles and finally the long air column terminating in the endpiece. The situation might be visualised as so listening to sounds coming from the other side of a room, with a thick heavy rug hung across the entrance. Through such a rug the slow air motion accompanying a low frequency noise would be clearly heard, particularly since the high frequencies would be largely filtered by the lax "diaphragm." If the soft rug could be pressed, it would become harder and thinner, providing less resilience—hence providing less resistance to the passage of high frequency sounds and more to low frequency sounds. A stretched rug would behave in the same way.

It appears that the diaphragm endpiece of a stethoscope accentuates the high frequency sounds not by properties inherent in the diaphragm, but rather by the effect of the compression and slight stretching of the

Obituary

LEONARD GREGORY PARSONS

M.D., M.D. LOND., F.R.C.P., F.R.C.O.G., F.F.R., F.R.S.

Sir Leonard Parsons, emeritus professor of child health in the University of Birmingham, was a prophet who was not without honour in his own country. But his name was almost as well known in Canada and the United States as it was here, and paediatricians all over the world will share in our loss.

From his earliest years he belonged to the Midlands, for he was born at Kidderminster and educated at King Edward's Grammar School, Aston, and at Birmingham University. After qualifying in 1903 he held resident posts at the Queen's Hospital in Birmingham and spent some years in general practice before taking a house-appointment at the Hospital for Sick Children, Great Ormond Street. In 1909 he took the M.R.C.P., and in the following year he was elected to the staff of the Birmingham Children's Hospital as physician to outpatients.

The hospital then had only 62 beds, whereas today there are over 300. Forty years ago the attention paid to the subject of diseases of infants and children was negligible, and the hospital was not associated with the medical school. Parsons set himself to promote the subject to the importance it warranted. Within five years his industry and enthusiasm had met its first reward and he was appointed to the specially established post of lecturer in diseases of children. Under his wise and thoughtful guidance paediatrics began to figure more prominently in the training of students.

During the 1914-18 war Parsons served with the R.A.M.C. in Salonika. For part of the time he was attached to the Serbian army and in 1917 he received the Order of St Sava. Soon after his return to civilian practice, he persuaded the medical faculty to approve the Children's Hospital for student instruction, and clinical classes were arranged. In 1920 he had convinced the university authorities of the importance of his subject, and when it was elevated to professorial status he was appointed the first professor of diseases of children in the university. During these and succeeding years, not only did he run a busy and exacting private practice but he continued to advance paediatrics by teaching, research, and writing. His industry and enthusiasm were indefatigable.

The next major development in the university department was in 1934, when clinical clerkship at the Children's Hospital was made compulsory for all students, and in 1943 Birmingham was one of the first universities to make paediatrics a special and distinct part of the final examination. Meanwhile increasing knowledge of the diseases of children led Parsons to appreciate that prevention was as important as cure but was not receiving the recognition it warranted. He saw clearly that the gap between these two sides must be bridged, and in 1930 he inaugurated discussions with representatives of Birmingham University, the Children's Hospital, and Birmingham city council. The war interrupted progress, but soon afterwards negotiations were resumed and in 1945 an institute of child health was set up in Birmingham. This institute fulfilled Parsons's ambitions and ideals and fused into one whole all aspects of child health. The scheme he evolved was the first complete one in this country, and up to the time of his death he continued to be an active member of the council.

Side by side with the university department of paediatrics, and again under Parsons's guidance, the Children's Hospital grew steadily in size, importance, and prestige. When the specially designed infants division was started over fifteen years ago, he went to infinite pains in the

study of the architectural design and gave invaluable help in rousing public opinion and raising funds for erection. The building was finished early in the war but could not be fully used until 1944. In October a special dedication ceremony was held, when the building was named the Leonard Parsons block. It will remain a memorial to his work for the hospital and the children of the Midlands. A London colleague of the hospital under Parsons as a friendly place, the visiting doctor was made to feel one of the keen workers and brought away something of his and enthusiasm he found there, for Parsons had found and developed a team spirit which was exemplified in the fine series of articles on the anaemias in childhood published under many names in the *Archives of Disease in Childhood* (1933-35). He was a man we all felt was a man of integrity and wisdom, who gave of his best to the best out of others. His editorship of *Archives of Disease in Childhood* with Seymour Barling, of *Diseases of Infancy and Childhood* was another example of his talent for a team.

Parsons was also an efficient administrator. In many years he represented the university on the General Medical Council, and from 1941 he was dean of the medical faculty. In the late war he was also a royal hospital medical officer for the Ministry of Health. From 1945 he was president of the Paediatric Association, of which he was a foundation member.

But there was also Parsons the research-worker. The many lectures which he was chosen to deliver were always something more than formal reviews, for they were warmed by his own knowledge, first-hand experience, and in striking surveys he linked the done in his own hospital with the done elsewhere. From the time when he gave his Goulstonian lecture in 1924, on the Wasting Disorders of Early Infancy, till his Witwatersrand lectures in 1947, on Nutritional Diseases, the deficiency diseases remained one of his great interests. Their closeness to him, for, as he once pointed out,

nutrition is quite easily recognised by Members of the public and publicists, but clinicians find it difficult to diagnose. Stimulated by the work of his colleagues W. N. Haworth, E. L. Hurst, and J. C. Drummond on the synthesis of ascorbic acid, it was natural that he should make a careful study of the clinical application of vitamin C, especially in relation to scurvy. Another chosen subject was diseases of the blood, and his Schorstein lecture at the London Hospital in 1938 was on the Hemolytic Anaemias of Childhood. As early as 1930 investigations into these anaemias were on in Birmingham, and the school played a large part in establishing that erythroblastosis is a hemolytic disease. His interest in every new idea was instant, and his Blair-Bell lecture to the Royal College of Obstetricians and Gynaecologists in 1918 he discussed the then theory of the influence of maternal rubella on congenital defects. But he steadily refused to lose sight of the forest for the trees, and in his Charles West lecture to the Royal College of Physicians in 1943 he once more insisted that paediatrics is not a specialty, but general medicine applied to a special period of life. He also lectured abroad. In 1931 he gave the Rachford lecture at the University of Cincinnati, and in 1941 the Black lecture to the Canadian Medical Association. In 1940 he was awarded the Moxon medal, and he was knighted in 1946. He was already a fellow of the Royal College of Physicians, of the Royal College of Obstetricians and Gynaecologists, and of the Faculty of Radiologists, and he was elected to the fellowship of the Royal Society in 1948.

On St Luke's day this year he was the Harveyan orator of the Royal College of Physicians, he was one of

Stoneman

chief of the Air, whose learned and entertaining conversation was broadcast last a few weeks ago he gave the Harben e Royal Institute of Public Health and died at his home on Dec 17, at the age of 57, of a still busy life

As "Those of us who knew Leonard Parsons gathered on committees, in the wards of his hospital, on examiners' panels, or in his own appreciation of his gentle, kindly nature, his wide sympathies, and his great love for home life was supremely happy and it was he who obtained the inspiration and strength for him so much in his work. His influence covered many points, and perhaps the future of his most important work has been the infant and child welfare work with clinical medicine and his facility for striking the right balance between prevention and cure of disease in childhood. He was a rather shy, Christian gentleman who will be remembered by friends all over the country. There will be many parents in the Midlands who will name him."

As "A. P. T.," writes A. P. T., "walking from our hospital Parsons told me that he had decided to devote much time as he could to the study of pediatrics. When I asked him why, he said there were three reasons. First, that he liked children, and second, he believed the problems of pediatrics were the most profitable to study while biological and clinical pathology were in their infancy, were relatively simple in comparison with adult diseases—and, he added with a laugh, he got on with simple things. With infinite patience and he built up the research departments at St. John's Hospital, and the record of his achievements not only of the shrewdness of his judgment of that rare power of sustained interest in so many projects fail. But he never grew specialist, he had a sense of the unity and knowledge that was wide as well as as not a quick or agile mind, but it was a gift, and he had the supreme gift of defining."

It was this and his integrity which brought him to an administrator in his later years, men might be wrong but they could not justly question his example inspired the school he served so well, and honours did not spoil him, to him as a humble seeker after truth and always searching. He had learnt the great lesson of quiet homes and first beginning to the undiscovered ends of nothing worth the wear of winning laughter and the love of friends as reward."

Leonard married Miss Ethel Mantle. She left a daughter and a son, Dr C. G. Parsons, followed his father as physician to the Children's Hospital.

HENRY MacCORMAC

C.B.E., M.D. EDIN., F.R.C.P.

Dr Henry MacCormac, consulting physician in skin to Middlesex Hospital, died at his home on Dec. 12, at the age of 71. His grandfather an old Belfast medical family. His grandfather Henry MacCormac, was said to know and was one of the first advocates of the treatment of consumption, which he held was "pre breathed air." His uncle, Dr MacCormac, who was present at the battle of Marston, acted as a surgeon in London and was five years of the English college. Henry MacCormac graduated M.B. at the University of Edinburgh in 1903, and after postgraduate study in Paris was appointed assistant registrar at Middlesex Hospital in London. He became medical registrar, and for a time acted as an assistant in the cancer research. Here his growing interest in dermatology

led him to study precancerous conditions of the skin, and in the reports of the department will be found his studies on the relationship of rodent ulcer with squamous carcinoma of the skin. In 1911 he was elected to the staff of the hospital as assistant physician, and he also became a member of the staffs of the Infants' Hospital, Vincent Square, the Seamen's Hospital, Greenwich, and St. John's Hospital for Diseases of the Skin.

Elliott & Fry

During the 1914-18 war he was consulting dermatologist to the British Expeditionary Force in France. Of this period H. W. B. writes "He was fired by an intense patriotism and a passionate determination to convince the Army authorities of the enormous wastage of manpower from skin diseases, much of which, as we know now, could have been prevented by adequate prophylaxis and efficient treatment. In the end, aided by others, he succeeded. If, perhaps, he underestimated the importance of pyogenic infection secondary to pediculosis corporis, he conducted with Dr W. D. D. Small an intensive campaign against scabies. He may be said to have made the Army scabies-conscious, and he took infinite pains to impress on medical officers the important diagnostic features of the disease and its complications, he described clearly the atypical varieties that might be encountered. It was, perhaps, an indication of his respect for tradition that the routine method of treatment he so strongly advocated and instituted wasunction with sulphur ointment twice daily for three days. He was, I think, the first to draw attention to the prevalence and seriousness of the mis-called 'seborrhoeic' dermatitis, which was so important a cause of disability among our troops in France. This condition was then usually diagnosed as impetigo and treated as such—with disastrous results, because one feature of these cases was their intolerance of banal antiseptic applications, such as mercurials and sulphur. MacCormac taught me that calamine liniment was probably the best local application, at any rate during the acute phase of the eruption. He rightly pointed out that what I later termed the 'status seborrhoeicus' aggravated the problem of scabies, partly because it favoured secondary pyogenic infection and infective eczematoid dermatitis, and partly because the patients were often in varying degree intolerant of sulphur ointment."

For his war services MacCormac was twice mentioned in despatches, appointed C.B.E. in 1919, and awarded the médaille de l'assistance publique. In 1917 he had been elected F.R.C.P., and in 1920 he became head of the skin department at Middlesex Hospital. In 1933 he was president of the dermatological section of the Royal Society of Medicine, and he also served a term of office as president of the British Association of Dermatology and Syphilology.

With his powers of observation and erudition he could, had he wished, have devoted himself to the more academic aspect of his subject and to research, but, although he made important contributions to literature, he preferred to concentrate upon dermatology as it affects the public welfare. He continued his campaign against scabies gave a broadcast, which was characteristic in its clarity and simplicity, and with considerable difficulty had an excellent film made and produced to illustrate the essential points in the aetiology and prevention of the disease. Later he interested himself in industrial dermatitis, and in his appointment as specialist medical referee his exact legal knowledge, his logical outlook, and his passion for justice made his opinions invaluable. It is

related that "he would drive down to some outlandish factory to inspect the actual environment and conditions, in order to be perfectly just in his judgment on industrial dermatitis cases." For such expeditions he received no additional remuneration. Recently, in spite of failing health, he succeeded—again with great difficulty—in launching a film on industrial dermatitis, which was admirably devised and produced. Outside his professional and public activities, he had the cultured man's love and respect for history and tradition, and he delighted to revive interest in great figures of the past. He wrote a memorable account of Robert Willan, and was responsible more than anyone for obtaining greater recognition of his pioneer services to dermatology.

"Far more than most" H. W. B. continues, "MacCormac was influenced by a sense of public duty, which accounted for his almost fanatical zeal during the first world war and afterwards as a civilian. He strove, as others have done less successfully to impress both the medical profession and the laity with the importance of certain common dermatoses in the lives and activities of the community. He was a man of impeccable—one might well say quixotic—personal and professional integrity. I have known him sarcastic and sometimes bitter when he met with frustration, injustice, or indifference, but he was incapable of meanness, unkindness, or selfishness. Serious to a degree when what he thought was right was impeded or neglected, he had an entrancing lighter side to his character. I have never had a more delightful companion. His sense of humour was of the more delicate, less obvious, kind, and he had—which is much rarer—a puckish appreciation of the comic, so that one of his treasured memories was that of Pelissier's *Follies*. He was a very good mimic, and his mimicry revealed his knowledge of the racial or social mannerisms and foibles of his victims. As a host he was generous without ostentation, and on more formal occasions one could rely upon his detecting a humorous situation if there were one. His high courage, and his humour, remained undimmed either by physical suffering or by the disappointment he felt at being unable to continue his work."

Lord Moran writes "Henry MacCormac was Ulster to the bone, and he had the qualities of good sense, forthrightness, and integrity, which we have come to associate with the North of Ireland, qualities softened in him by the graces of an old tradition. For his forebears had won distinction in medicine before Jane Austen began to write—perhaps even in this democratic age that is no disadvantage—and his grave and gentle courtesy with humble folk came from a day before men congregated in great towns, so altering life. He was a simple soul, unconscious of his worth, and when a signed copy of the *Gathering Storm* was sent to him, he treasured it and kept it always in his room, he was a man of strong loyalties, though his feelings seldom came to the surface. Men liked him for the reasons known to men, and long ago cries of 'Henry, Henry' would greet his appearance at the Savile Club, before he was taken off to the bridge room. In the branch of medicine which he practised he was a master, striving always to understand what was happening beneath the surface, for he was not a man to be content with labels, and in the business of the world his opinion was valued by the Royal College of Physicians, of which he had been a councillor and Lumsden lecturer."

In 1931 Dr MacCormac married Marion, daughter of Mr B. C. Broomhall, F.R.C.S., of Tai Yuan Mission Hospital, China. She survives him with one son.

SYDNEY WATSON SMITH

M.D. EDIN., F.R.C.P., F.R.C.P.E.

Dr S. Watson Smith, a past president of the British Medical Association, died on Dec 15. He studied medicine at St Andrews before going to Edinburgh, where he qualified in 1903. Despite delicate health he insisted on giving up his Dundee practice during the 1914-18 war to serve with the R.A.M.C. On demobilisation he settled in Bournemouth where from 1924 he restricted himself to consultant practice. He was chosen to preside over the B.M.A. when it met there in 1934. The editor of the *Boal of Bournemouth*, he spoke and wrote sensibly on climatology, and in 1936 and 1937 he wrote constructively on the lessons to be learnt from the Bournemouth typhoid epidemic. He was the chronicler of the B.M.A. world tour which he led to Australia in 1935.

Public Health

Poliomyelitis

In England and Wales notifications of poliomyelitis during the week ended Dec 18 were paralytic 82 (non paralytic 25 (31), total 107 (104). The figures the previous week, compared with which there was a total decrease of 3, are in parentheses.

Pest Destruction by Fog

The insecticidal fog applicator known as 'TIFA' has been developed from the fog generators used in the war. The makers claim that this apparatus, operated by one man, can fill 15,000 cubic feet of room space with fog in a minute, or blanket 30 acres of ground in an hour given favourable atmospheric conditions. The machine illustrated, mounted on a Jeep, was in Sardinia during the malaria eradication campaign in 1947; it is shown fogging the cathedral church Bon'Arna, Cagliari. Various petroleum solvents make satisfactory fogging fluids, and to these may be added insecticides such as D.D.T., B.H.C., or pyrethrum; droplet size of the fog can be adjusted between 0 and 200 μ . The power is supplied by a 6 h.p. petrol engine, which drives a blower and pumps, and the machine will disperse 10½-53 gallons of insecticide per hour, according to the particle size adopted. The

Fog applicator in action

applicators, with trained operators, can be hired from health authorities.

One of these machines was used this summer in the Lincolnshire village of Cranwell at the time of the poliomyelitis epidemic, and Dr J. Scholey, the medical officer of health, writes as follows:

"Three houses in which cases had occurred were fogged with a solution of D.D.T. with 0.1% of pyrethrum in kerosene. This was done by closing all the doors, windows except one which admitted the nozzle of the machine. In a matter of about five minutes the house was filled with the 'fog,' which is delivered under pressure. The amount of insect life destroyed is quite surprising and most illuminating. A room which was comparatively free from flies and the like yielded scores of insects. Out of fly infested places were then chosen and were dealt with by delivering a fine 'fog' of 5% D.D.T. in kerosene. Ponds, drains and open sewers produced swarms of insects which were all quickly destroyed. Here I think a word of warning should be issued, as the indiscriminate use of the machine over certain sewage plants which depend on insect life for their effective function could be definitely detrimental."

There is no doubt that the TIFA fog is a most effective means of destroying flies and other insects and extremely thorough and swift in action.

The machines are extensively used for public health work abroad some 52 being known to be operating in 40 different countries.

Notes and News

CHESTER REGISTRARS' MEETING

ng of the Manchester Region Registrars Group
r R M FORRESTER, who was in the chair, said
up had pressed for a proper consultant-registrar
registrars disagreed with the way the Minister
as proposing to achieve this. The professional
shed by the Minister had regarded his proposals
able. Replacement of registrars by general
assistants could not be contemplated by hospitals,
r the general practitioners themselves. Dr
mentioned the unsatisfactory alternative employ
to the 1100 displaced registrars. The most senior
is first to be dismissed, and neither the Armed
the Colonial Medical Service were attractive, as
rars had already served in the Forces and many
nily responsibilities. Entry into general practice
ely difficult for registrars. The Minister had
in drawing up his scheme he had not been
y the Treasury and no saving would be effected
ng registrars from the hospital service to any
cal service. Dr Forrester put forward three
hich might help to solve the registrar's problem:
e expansion of consultant services, (2) improve
ditions in general practice and (3) extension
e of senior registrar appointments, whose length
with the openings in the consultant service. As
finite maximum tenure was laid down there would
ing of new entrants.

REDMAN pointed out that such an extension would
period of insecurity before the registrar knew
was to get a consultant post. He suggested, as
ive, the creation of junior consultant posts. This
as criticised by some members on the ground
services of a fully trained consultant would be
less than a consultant's pay. Members agreed,
y 60 votes to 22 that the present emergency can
far as is possible by extending the consultant
ad by the creation, if necessary, of junior con
sultants. A 'junior consultant' was defined
to be paid at a salary intermediate between senior
id consultant, and with full clinical responsibility,
have the right to promotion to full consultant's
embers unanimously adopted the chairman's
of-policy as the basis for future discussion and
ad they rejected by an overwhelming majority a
hat the principle of increased tenure of senior
ppointments does not commend itself as generally

TWO PATIENTS SAW POLIOMYELITIS

th comparing two books¹ written about themselves
rs from poliomyelitis. Gerald Webster gives a
ward account of the life of a disabled person as
longer be lived we may hope in a Welfare State.
' had a hard time in Australia and England as a
uld and young man but even so the security
was emotional rather than financial. It is a pity
as not the capacity to describe his own feelings
y as he does those of others. Very occasionally
shines out from its context and momentarily lights
ene but for the most part the reader must use his
gnation to understand what the author does not
itz Plagemann evidently has far more experience
of writing and can—almost too readily—give us
hts and emotions. He developed the disease as an
id not as did Mr. Webster in childhood. Yet for him
litis was almost incidental. Half the book is an
of his life as a pharmacist in the American Navy
is last war and he thinks that there may well be a
n between his response to that experience and the
the disease. Undoubtedly he seized it as a welcome
om responsibility and this is the crux of the book.
age poliomyelitis patient of his age is optimistic and
trying hard to get better but this young man
the famous Warm Springs settlement only as a
ere one becomes acclimatised to disability. In the

emotional conflict between his paralysis and its value as a
refuge he has no energy left for recovery.

In both men, however, the dominant factor is the imperative
need for security—not a financial or even a social security,
but a true emotional security on which to base the new life.
They convince us that the adult injured by poliomyelitis must
first of all believe in the possibility of considerable recovery
and work wholeheartedly for it, but that he must at the same
time be willing to accept some makeshift and perhaps per
manent compensatory movements. Then, in spite of even
widespread paralysis, he may still live constructively. Even
when Gerald Webster had won a degree of financial security,
his future was by no means certain until he had learnt that
a cripple can still be accepted as a man both by the world
about him and by himself. The two books remind us that
for those treating infantile paralysis the most important
aspect of the patient is his mind, and its influence on recovery
and readjustment.

University of London

The title of professor of clinical pathology in the university
has been conferred on Dr. Montague Maizels, reader in clinical
pathology at University College Hospital Medical School.

University of Bristol

At recent examinations the following were successful

Final Examination for M.B. Ch.B.—R. M. Barnes, Marianne A.
Barry, Monica B. Bishop, K. A. Boulton, Luba Epstein, B. R. W.
Evans, Hella R. Fluss, R. F. Harvey, M. E. Hincks, K. R. Kidd,
G. A. Pilkington, J. F. Rowland, Rachel D. R. Sarseni, Mildred M. C.
Shaw, D. T. I. Stuttaford, Ghette M. Tebbutt, P. A. Titterton,
Patricia Vowles and Harold Maxwell (in Group I completing the
examination).

D.P.M. (Part II)—J. A. Ardis, K. W. Aron, E. C. Turton.

University of Durham

On Dec. 15 the following degrees and diploma were con
ferred

M.B. B.S.—Meryl A. Christian, J. A. Eykelboom, J. R. J.
Glavin, C. St. J. E. Harding, Marjorie Hepple, D. D. Hobbs,
Shirley McTaggart, Brian Metcalfe, Shirley M. C. Nuttall, Lola V.
Stafford, Anne W. Watts.

D.P.H.—J. F. McGarity.

University of Manchester

At recent examinations the following were successful

Final M.B. Ch.B.—H. G. Arnall, R. B. Falgh, J. M. Midgley,
R. E. Raworth, Gertrude H. G. Robinson (old regulations),
Derek Ashworth, Margaret Bentley, Constance M. Bevan, J. C.
Canney, E. H. Cooper, Donald Davies, Brian Didsbury, Jacob
Ella, G. R. Gates, Ronald Hinchcliffe, J. T. W. Howe, Geoffrey
Howitt, T. R. Hunter, Arnold Hyman, J. E. Kench, J. H.
Litchford, M. B. Rab, Carolyn C. Rigby, Kathleen M. Rushton,
Janet Savatard, Harold Selcon, Lorna J. Shankland, Alan
Sippert, Geoffrey Sullivan, D. W. Sumner, S. E. Sutton, Olive
M. Thomas, C. F. H. Vickers, Margaret R. Walley, Brian Ward,
G. R. Whittaker, David Wolman (new regulations).

D.P.M.—Zygmunt Finkelstein, L. G. Nicol, Margaret I. Platt,
Susanne Sheffer, T. P. Smith.

University of Edinburgh

On Dec. 15 the following degrees and diploma were conferred

M.D.—E. D. Caldwell, T. M. Chalmers, E. N. Moyes, C. Scott,
Russell, J. T. R. Russell, J. J. Stevenson.

Commended In absentia

M.B. Ch.B.—H. F. Acheson, W. D. A. Birch, G. Y. Cheyne,
Phyllis Connor, B. S. Dorfman, I. A. Fraser, A. D. Gentle, John
Grant, E. R. Henry, Brenda M. Johnson, Hazel M. Lazarus,
Margaret E. Loudon, Alastair Macaulay, A. R. Manners, W. P.
Mazur, I. A. Mitchell, P. T. Monard, Robert Renton, P. F. F.
Rushforth, T. M. N. Salvesen, L. E. S. Sandison, G. A. Steele,
J. F. Stephen, E. B. Tague, Nancy M. Tweedie, Stodart, Mary B.
Watson, J. S. Whittaker, T. W. Wilkinson.

D.M.R.T.—J. D. Abbott.

University of Sheffield

Dr. D. E. Price has been appointed honorary lecturer in
pathology.

Royal Faculty of Physicians and Surgeons of Glasgow

Sir John Parkinson will deliver the Finlayson lecture to
the faculty at 242, St. Vincent Street, Glasgow on Wednesday
Jan. 10, at 5 P.M. He is to speak on Symptoms in Cardiac
Diagnosis.

Institute of Neurology

A film will be shown at the National Hospital, Queen
Square, London W.C.1, on Friday Jan. 5, at 5 P.M., of an
hemispherectomy performed by Mr. R. A. Krynauw, F.R.C.S.E.,
head of the department of neurosurgery, Johannesburg
Hospital.

Caribbean Conference

The British Medical Association is holding, at Port of Spain, Trinidad, from Jan 8 to 13, a conference at which Dr Guy Dain will take the chair. Dr Dain will be accompanied on his visit to the West Indies by Dr H B Morgan, who will also speak at the conference.

Course on Rheumatic Diseases

A course on the chronic rheumatic diseases is being held at the rheumatism unit of St Stephen's Hospital, Fulham Road, London, S W 10, on Saturday and Sunday, March 3 and 4. Dr Russell Bram, F.R.C.P., will give the inaugural lecture. Further details can be had from the medical registrar of the unit.

Cytology of Bacteria

A joint meeting of the microbiological panel of the society of Chemical Industry and of the Society for Applied Bacteriology on this subject will be held on Wednesday, Jan 10, at 2.15 P.M., at 11, Chandos Street, London, W 1. Prof R J V Pulvertaft, F.R.O.P., will open the discussion.

W H O and Alcoholism

A committee of the World Health Organisation's expert panel on mental health met in Geneva this month to discuss alcoholism as a public health problem. According to the *New York Times* (Dec 17) the committee has recommended that special clinics be set up in general hospitals throughout the world. It also urged the establishment of a world clearing centre for scientific information on the causes and cures of alcoholism.

College of Food Technology

After negotiations between the Ministry of Education, the Ministry of Food, and representatives of sections of the food industry, it has been decided to set up a National College of Food Technology in London about next September. Students will be drawn from the food industry at the age of 23 or over, to receive advanced training. The board of governors has been appointed by the Ministry of Education and will include Mr Frank Shires, of the Food Manufacturers Federation, as chairman, and Mr John Hammond, F.R.S., reader in agricultural physiology in the University of Cambridge, as vice chairman.

Sale of Peckham Health Centre

Subject to the approval of the Ministries of Health and Education, London County Council is shortly to acquire this centre, for the sum of £60,000. The L.C.C. education services are at once to have the use of the swimming bath, gymnasium, and lecture hall. Within the next two years an antenatal centre is to be set up in the medical rooms of the centre, and the ground floor is to be adapted for use as a day nursery. Later it is planned to establish a general practitioner health centre, maternity and child welfare centre, and dental centre to serve 26,500 people, and a medical research unit. This full scheme will cost nearly £126,000. The new facilities will to some extent continue the work of the old Peckham Health Centre, but as it will not be in the original form it has been agreed that the building shall not bear the name of the Pioneer Health Centre or the Peckham Health Centre.

Payment of Advisory Appointments Committees

The Ministry of Health has announced in a circular (R.H.B. [50] 124) new arrangements for the payment of advisory appointments committees constituted after receipt of the circular. The Minister, this says, is of opinion that 'it is not appropriate that members of these Committees should receive fees (bearing in mind that members of Boards themselves and their normal committees are not entitled to be paid fees). Nevertheless these members should be able to claim compensation for any loss of earnings and for additional expenses, subject to the conditions applied to members of boards and their committees generally. The one exception is a consultant appointed from outside the region to serve on an advisory appointments committee in the case of a post at a non-teaching hospital, or on a joint advisory appointments committee set up where it is proposed to appoint the same person in both a teaching and a non-teaching hospital. This member may be remunerated at the rate of 7 guineas a day or 4 guineas a half-day provided that he is not drawing the full salary for whole time employment.

Yorkshire Society of Anaesthetists

A meeting of this society will be held at 8 P.M. on Jan 3, at Leeds General Infirmary, when Dr speak on Anaesthesia for Babies and Children.

International Exhibition of Medical Arts

This exhibition and a series of international surgical meetings will be held at Turin from June 21 under the auspices of *Minerva Medica* Italian Medical Association. Further information had from Prof S Teneff, Palazzo delle Esposizioni, Torino, Italy.

Sir Gordon Gordon Taylor has left London on a visit to Pakistan arranged by the British Council.

Copies of the proceedings of the third conference on works safety, held at Scarborough from Sept 29 to Oct 1, may now be obtained from the Association of British Manufacturers, 166, Piccadilly, London, W 1 (5s post).
